Ag have high TBOD where as those lead by As, Sb, Sn and Cd have low TBOD. Such deep insight can only be revealed by calculating the TBOD, or the geno for each chalcogenide crystal. It is anticipated that additional calculations on other chalcogenide crystals will make a reasonable size database to be even more useful.

IGF Models

Ceramic materials are usually polycrystalline and contain many types of defects. One of the defective structures that is ubiquitous in Si_3N_4 and SiC is a thin layer of glassy matter, approximately 1–3 nm thick situated between different crystalline grains in the sintered samples (Clarke, 1987; Tanaka *et al.*, 1994; Subramaniam *et al.*, 2006; Kleebe, 1992). These so-called intergranular glassy films (IGFs) are the key factor in controlling the mechanical properties of Si_3N_4 . The glassy film contains a varying mixture of Si, O, and N with an almost constant thickness depending on sintering adds. The films can intersect at triple junctions of the

with identical interfaces within the models and contain only one IGF in order to maintain the periodicity of the model (Ching *et al.*, 2010; Rulis *et al.*, 2005; Chen *et al.*, 2005; Ching *et al.*, 2006a; Misra *et al.*, 2007; Ching *et al.*, 2009).

The electronic structure, density of states, interatomic bonding, partial charge distribution for this large IGF model are obtained and analyzed focusing on the interfacial regions between bulk $\beta\text{-Si}_3\text{N}_4$ and the Si-O-N glass layer with different orientations (Ching *et al.*, 2018). All the interatomic bond pairs and BO values are calculated and fully analyzed. Fig. 15 shows the distribution of BO vs BL in this IGF model where the location of these bonds in the model are designated with different symbols and colors.

Fig. 12 BL vs BO in 25 chalcogenide crystals listed in [Table 6](#).

This illustrates the versatility of using the BO concept to relate to their physical structure and properties. We have further calculated its mechanical properties of the model (Adhikari *et al.*, 2019b) in order to link the subtle connections to TBOD and PBOD to its mechanical properties, and to demonstrate the use of TBOD in applying to systems beyond the simpler crystalline phases. The TBOD of the IGF is $0.0512 \text{ e}^-/(\text{\AA})^3$ and can be compared with the TBOD of crystalline $\alpha\text{-Si}_3\text{N}_4$, $\beta\text{-Si}_3\text{N}_4$, $\text{c-Si}_3\text{N}_4$ and $\text{Si}_2\text{N}_2\text{O}$ listed in Table 1 in Section 3.1 above. The TBOD for $\beta\text{-Si}_3\text{N}_4$ and $\text{Si}_2\text{N}_2\text{O}$ are $0.0512 \text{ e}^-/(\text{\AA})^3$ and $0.0432 \text{ e}^-/(\text{\AA})^3$ respectively. This seems to suggest that the IGF model has retained its crystalline TBOD. Apparently, the weaker PBOD within the glassy region is compensated by the increase in the PBOD at the interfacial region. This appears to be a natural explanation as to why the presence of IGF in structural ceramics such as silicon nitrides and Si carbides are ubiquitous.

Application of TBOD Different Glasses

Insulating Glasses

Over the years, we have done a lot of research related to amorphous SiO_2 (a- SiO_2). In recent years, we rely on the concept of TBOD for interpretations on various doped and hydrated silicate glasses with more complex structures. It all started with a periodic model with 54 SiO_2 molecules (Ching, 1981). The beauty of this model is it has small bond angle (BA) and bond length (BL) distortions, a near ideal distribution of ring structure and no over- or under-coordinated Si or O atoms. Such model is very difficult to construct because of the strong directional Si-O bonds across the periodic boundary. This model was later expanded to a $2 \times 2 \times 2$ supercell with 1296 atoms with other additional refinements, making it an ideal model for many studies on a- SiO_2 and related glasses (Li *et al.*, 2014; Baral *et al.*, 2017; Baral and Ching, 2017; Baral *et al.*, 2019; Huang and Ching, 1996).

With the development of the novel concept of TBOD within last years, application of TBOD to silicate and other glasses is obvious. Simultaneously, the adoption of *ab initio* molecular dynamics (AIMD) makes the reliance on the original 162-atom a- SiO_2 model less important and the size of more complex models can be made more flexible since AIMD simulation with more than 1000 atoms is still impractical. In the following, we provide examples of specific application of TBOD to several insulating glasses.

An obvious extension from the well-studied near-perfect continuous random network (CRN) a- SiO_2 model with 1296 atoms is the systematic replacement of Si by Ge to amorphous $\text{Si}_{1-x}\text{Ge}_x\text{O}_2$ models with x ranging from 0 to 1 (Baral *et al.*, 2016). The x -dependence of the variations of the properties are analyzed and critically compared with available experimental data. The mass density, volume, TBOD, bulk mechanical properties and refractive index are found to vary linearly as a function of x . For $x = 0.5$, we constructed six different kinds of particle immersion models to test the effect of inclusion of spherical particles of different sizes

Fig. 15 (a) BO vs BL distributions for all atomic pairs in the relaxed IGF model. (b) Same plot as (a) but with bond pairs from the bulk region removed showing on those in the IGF (region III) and in the transition layer (region II).

of one glass in the medium of the other glass. This is illustrated in **Fig. 16**. The results show that particle size does affect the properties of particle immersion. These calculations provide a deep insight on the properties of mixture and nanocomposites of a-SiO₂ and a-GeO₂ and the role of the TBOD in affecting their properties originating from the slight difference in Si-O and Ge-O bonding.

AIMD has been applied to construct seven sodium silicate glass models with Na₂O concentration ranging from 0 to 50 mol % (Baral and Ching, 2017). All models are based on the 162 atom near-perfect CRN model for a-SiO₂ introduced earlier which facilitates the model construction. AIMD is necessary since the introduction of Na ions disrupts the network structure and their interactions. The structure of the simulated (Na₂O)_x(SiO₂)_{1-x} glasses are critically analyzed and validated by experimental data. The TBOD is used to characterize the internal cohesion of sodium silicate glass, which decreases with the increasing Na content as shown in **Fig. 17**. The calculated mass density and refractive index increase with *x* while the band gap decreases with *x* which are in good agreement with experimental data. The calculated mechanical properties of these models indicate that alkali-silicate glass tends to be unstable for *x* greater than 0.4 due to total destruction of the SiO₂ network consistent with the TBOD data.

The AIMD simulation on Na₂O-doped glasses was extended to models of Li- and K-doped single and mixed alkali silicate glasses with two different molar concentrations of alkali oxides. The structural environments and spatial distributions of alkali ions in the 10 simulated models with 20% and 30% of Li, Na, K and Li-Na, Na-K in equal proportions were studied for subtle variations among these models. Results on the electronic structures, interatomic bonding, mechanical and optical properties are compared with other simulations and are in good agreement with the experimental data. TBOD is used to characterize the internal cohesion in these alkali-doped models and to explain the mixed alkali effect (MAE) in their bulk mechanical properties, but is less obvious in other physical properties studied (Baral et al., 2017). It is also shown that Li-doping deviates from expected trend due to the much stronger Li-O bonds than those of Na-O and K-O bonds. The approach we used in alkali-doped silicate glasses is in contrast with other existing studies that are based purely on geometric characterizations. The study on alkali-doped Silicate models was further extended to include the effect of water (Baral et al., 2019). Silica-water interaction plays an essential role for the mechanical strength and chemical durability of alkali-doped silicate glasses. It was confirmed that water in the solvated bulk models can either dissociate or remain as H₂O molecule depending on the local distribution and specific alkali elements. We also confirmed that the mechanical strength of bulk alkali silicate glasses is enhanced by hydration with some evidence that mixing of

Fig. 16 (a) Polyhedral structures of Part I for $(a\text{-SiO}_2)_{1-x}(a\text{-GeO}_2)_x$ glass, $0 \leq x \leq 1$. (b) Two dimensional and three dimensional illustration of 6 models of Part II for spherical particle inclusion of one glass into the medium of other glass.

alkali ions tends to degrade the strength of the hydrated glasses. Again, TBOD is used here as a key parameter to unravel the atomistic origin of the internal cohesion and strength of glasses in different environments.

The above studies are further extended to even more complex glasses by adding Al_2O_3 to the Na-doped silicate glasses (Baral *et al.*, unpublished), or the sodium aluminosilicate (NAS) glasses. In this case, AIMD simulation with larger models of about 700 atoms are necessary. Four such NAS glass models $(\text{SiO}_2)_{0.6}(\text{Al}_2\text{O}_3)_{0.4-x}(\text{Na}_2\text{O})_x$ for $x = 0, 0.135, 0.20$ and 0.24 corresponding to ratio Na/Al ratio of 0.0, 0.5, 1.0 and 1.5 are constructed. The electronic structure, bonding, partial charge, mechanical and optical properties of these models are calculated and analyzed in detail. These results enable us to understand the role played by Al and Na in silicate glass network and the changes in glass properties when glass composition varies. We also find that the silica network can largely recover after removing the Al_2O_3 component but with weakened internal cohesion and strength compared to pure silicate glass as characterized by TBOD.

The above examples simply demonstrate the effectiveness of using TBOD as the geno for insulating glasses, a step beyond in applying just to ceramic crystals. In the following, we further demonstrate the application of TBOD to another very different type of glasses, the metallic glasses.

Metallic Glasses

$\text{Zr}_x\text{Cu}_{1-x}$ and $\text{Zr}_x\text{Cu}_y\text{Al}_z$

Metallic glasses (MG) are another class of non-crystalline materials but completely different from the insulating glasses discussed above. This is because metallic bonding is multi-atomic in nature, completely different from the covalent or ionic bonding where the definition of BL is well-accepted as the distance between the two atoms that form the bond. In MG, the geometric parameter of BL has no meaning since all atoms within certain distance of separation can contribute to metallic bonding. As such, any theory or scheme based on the geometric parameter of BL is ill-defined. This is a highly contentious issue in MG community that is still hotly debated. However, the concept of TBOD, being a quantum mechanical metric, still applies without any compromise as long as all the BO values of the contributing atoms nearby are counted. This point has already been strongly argued for in reference (Ching 2019) with examples. Here we reiterate them and

Fig. 17 TBOD vs x in $(\text{Na}_2\text{O})_x(\text{SiO}_2)_{1-x}$ glasses.

Fig. 18 Illustrative sketch of models for $\text{Zr}_{50}\text{Cu}_{50}$ (left) and $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$ (right). Red, Zr; Green, Cu; Black, Al.

with some additional evidences. The two MG systems discussed here are (1) binary $\text{Zr}_x\text{Cu}_{1-x}$ glass ($x = 0.32 - 0.54$) and (2) ternary $\text{Zr}_x\text{Cu}_y\text{Al}_z$ glass. All models have 1024 atoms and fully relaxed using VASP without any volume constraint. The initial starting model is generated from quenching with classical MD. The electronic structure and interatomic bonding of these MG models are fully calculated (Ching, 2019). Fig. 18 shows the ball and stick sketch for $\text{Zr}_{50}\text{Cu}_{50}$ and $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$. For both MG models, additional simulations were carried out for the MG under compression by reducing the volume of the cell 5% and 10% respectively. In Table 7, we list the TBOD for of $\text{Zr}_{50}\text{Cu}_{50}$ and $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$ (p0 for the equilibrium model and p1, p2 their compressed models). It can be seen that the TBOD is increased when under compression.

In Fig. 19 we show the BO vs BL plots for the two MG models $\text{Zr}_{50}\text{Cu}_{50}$ and $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$. Here we must emphasize that the “BL” refers to distance of separation between 2 metallic atoms whereas the BO is calculated by summing the contributions to the metallic bonding from all other metallic ions within the distance of 4.5 Å of these two atoms. These plots clearly shows that for a fixed “BL” there are many possible BO values, and for a fixed BO value, there could be a range of “BL” or the distances of many atomic pairs having this BO value. This fact unequivocally refute any assertion of using geometric BL in MG in describing their structure and structural units.

Fig. 12 shows the dependence of TBOD on x for the binary $\text{Zr}_x\text{Cu}_{1-x}$ glass. The TBOD steadily decrease as x increases but not in a perfect linear dependence indicating that TBOD can reflect more hidden details in the variation. This has been discussed in Ching (2019) in comparison of some experimental observations (Li et al., 2008) based on preliminary data.

Atomic scale investigation beyond using classical parameters for structural characterization in MG is still in the early stage of development. There are tremendous opportunities in research on MB with 2-D structures or with crystallite inclusions as precipitates. All such expansion in the scope of research will expand the range of applications not envisioned, but certainly require will high-level analysis and modeling using the new concept of TBOD and PBOD (Fig. 20).

Vitreloy ($\text{Zr}_{41.2}\text{Ti}_{13.8}\text{Cu}_{12.5}\text{Ni}_{10}\text{Be}_{22.5}$)

Vitreloy is a special class of MG also coined as bulk metallic glasses (BMG). It was first reported in 1993 (Peker and Johnson, 1993) due to the desirable ability to form in bulk instead of thin ribbon using fast cooling (Jun et al., 1960). We reported the structure and electronic bonding for a particular BMG vitreloy ($\text{Zr}_{41.2}\text{Ti}_{13.8}\text{Cu}_{12.5}\text{Ni}_{10}\text{Be}_{22.5}$) (Hunca et al., 2016). For such multi-component BMG,

**Fig. 19** BO vs BL in $\text{Zr}_{50}\text{Cu}_{50}$ (top left) and $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$ (top right). Percentage of the TBOD components in $\text{Zr}_{50}\text{Cu}_{50}$ (lower left) and $\text{Zr}_{50}\text{Cu}_{40}\text{Al}_{10}$ (lower right).

classical MD is not useful since reliable potential is nonexistent and accurate AIMD simulations is the only way. The size of the model was limited to 512 atoms. **Fig. 21** shows the sketch of this vitreoloy model and **Fig. 22** display the total and partial pair distribution function for this vitreoloy, which is in good agreement with experiment (Gerold *et al.*, 1999). Detailed calculation of the electronic structure and bonding at the DFT level was obtained for the first time (Hunca *et al.*, 2016).

Fig. 23 shows the calculated total and atom-resolved PDOS for this model. **Fig. 24** is a Pei chart showing the contributions to the TBOD from all pairs of atoms in vitreoloy. It is not surprising to see that Zr-Zr and Zr-Cu have the highest percentage of contribution to TBOD since they have the top two atomic composition. But the Zr-Ti pair has 12.64% contribution compare to only 8.38% from Zr-Cu pair even though Ti has far less atomic percentage of only 3.8% compared to 12.5% for Cu. This can only be attributed to the strong Zr-Ti bond compared to Zr-Cu bond. We again use this example to advocate the use of TBOD and PBOD to characterize the interatomic bonding in multi-component glasses such as vitreoloy.

Fig. 20 Dependence of TBOD on x in binary Zr_xCu_{1-x} glasses.

Fig. 21 A configuration from AIMD simulation for vitreoloy. Red, Zr; blue, Ti; green, Cu; yellow, Ni; gray, Be.

We believe that the TBOD is correlated with the glass forming ability (GFA) in conventional MG and in BMG. The reason is quite simple, for complex glasses, metallic or insulating, the use of pure geometric parameters for their characterization is not tenable or reliable. It has to rely on quantum mechanical treatment to accurately account for both the structure arrangement and the interatomic interaction.

Metal-Organic Frameworks Glasses

Zeolitic imidazolate frameworks (ZIFs), a subset of metal-organic frameworks (MOFs) have recently attracted immense attention (Furukawa *et al.*, 2013). Many crystalline ZIFs (c-ZIFs) have zeolite structure with large-porosity that are ideal for molecular encapsulation (Banerjee *et al.*, 2008; Tran *et al.*, 2011). More recently, non-crystalline or amorphous ZIFs (a-ZIFs) with similar short-range order are of great interest because it represents another class of organic-based glass. We have constructed a unique a-ZiF model with 918 atoms that maintains the network topology analogous to silica. The same 162-atom a-SiO₂ model (Ching, 1981) discussed in the beginning of Section 4 is used as the seed model. In the network, the corner-sharing SiO₄ tetrahedra are replaced by MN₄ tetrahedra (M = a metal, Zn in this case) linked by organic linker imidazolate (IM) (C₃N₂H₃)⁻ anions (Adhikari *et al.*, 2016). The fully relaxed structure of this a-ZiF is illustrated in Fig. 25. This unique a-ZiF model maintains all the structural integrity required for the metal organic glass and has since be employed in many recent studies (Adhikari *et al.*, 2016, 2018; Wang *et al.*, 2019).

Fig. 26 Illustration for compression and extension. Stress vs strain in percentage. Compression is shown on the left and expansion on the right side. The inset shows the ball and stick diagrams of a complex organic/inorganic glassy alloy at different stages of compression/expansion: (a) compressed with a strain of 33.75% into a metallized a-ZIF; (b) the equilibrium a-ZIF model and; (c) expanded a-ZIF model at a tensile strain of 37.6% with large porosity and super-soft framework.

A computational study on the deformation behavior of this unique a-ZIF model by simulating step-wise compression and expansion with strains between -0.389 and $+0.376$ is recently accomplished by us (Adhikari *et al.*, 2018). This is illustrated in Fig. 26 starting from the model p0 at equilibrium to model p21 at high compression and model t19 at the end of extension. An insulator-to-metal transition is observed at pressure of 51 GPa in step p19 leading to a multicomponent light weight amorphous metallic alloy of low weight density of only $3.68 \text{ g}/(\text{cm})^3$. An amorphous-to-amorphous phase transition is observed due to the sudden formation of N-N bond pairs at this compression. This is illustrated in Fig. 27 where the BO vs BL distribution for all the bond pairs for model p19 is plotted. The N-N bonds with BL ranging from $1.27 \text{ \AA}$ to $1.50 \text{ \AA}$ and large BO values (indicated by star symbol) was not observed in the similar plot for the preceding model p18. Also apparent are the formation of three H-H bonds in forming the H₂ molecules. Systematic expansion of a-ZIF retains the framework softness until it fractures at high strain. This large scale simulation again demonstrated the pivotal role played by TBOD in understanding the metalization process and also the in overview of the change in TBOD and PBOD during the deformation process. In Fig. 28, we plot the TBOD and the PBOD at each strain during the deformation. It can be seen that the sudden appearance of the PBOD from N-N pairs at model p19 immediately after the model p18.

Extension to Transition Metal Random Alloys

Why do we extend this chapter to include random transition metal (TM) alloys which are neither ceramics nor glasses? They are complex metallic systems where theory and modeling techniques are still in early stage of development. TBOD as a geno for materials can substantially contribute to the advancement of this sector of materials science.

Fig. 28 Change in bonding throughout the deformation: (a) Total bond order density (TBOD) vs strain % for compression and expansion. The color segments show the contributions (PBOD from different bond pairs). (b) Number of bonds vs average bond order for p19, p0 and t19.

High Entropy Alloys

High entropy alloys (HEA) are a relatively new class special multicomponent metallic alloys in FCC, BCC or HCP lattices or in mixed phases with many promising applications (Gao *et al.*, 2016). It originated more than 20 years ago (Yeh *et al.*, 2004). These unique alloys, in sharp contrast to traditional alloys based on one or two principal elements, have four or more atomic components resulting in unusually high entropy of mixing. These solid solution alloys in equal or near-equal molar composition are also named as multi-principle element alloys (MPEAs) (Cantor *et al.*, 2004). HEA have attracted an ever-increasing interest from academia and industries in recent years and is now an emergent new area of alloy research mainly because of their potential promising applications and new science for its fundamental understanding (Ye *et al.*, 2016; Miracle and Senkov, 2017; Pollock and Van der Ven, 2019).

Since the fundamental theory for the formation of HEA is still lacking and numerous different modeling techniques and computational tools are being rapidly developed (Ding *et al.*, 2018; Guo *et al.*, 2011; Sun *et al.*, 2017a; Jiang *et al.*, 2004). We feel that TBOD can play a critical role for this class of alloys. Although HEA and vitreloy discuss above are both disordered alloys, HEAs are more suitable for systematic application to materials informatics based on data from DFT calculations because the structural part of the alloy sampling is simpler to model than in BMGs. To this end, we have recently constructed nine realistic random solid solution models in BCC lattice and calculated their electronic structure and mechanical properties for possible correlations with TBOD and PBOD. The motivation is to design the light weight, high strength, ductile, bio-compatible, corrosion resistant, cost effective HEA for bio medical applications such as in bone, tissue and joint replacements or implements (Koval *et al.*, 2019; Nguyen *et al.*, 2018; Yuan *et al.*, 2019; Todai *et al.*, 2017). These need atomic scale understanding. The 9 alloys are: TiNbTaV, TiNbTaZr, TiNbTaZrMo, HfNbTaV, NbTaTiVZr, TiZrHfNbTa, TiHfNbTa, TiZrHfTa, TiZrHfNb. Six of them have 4 components and the other three have 5 components. Some preliminary results have been obtained (Ching *et al.*, unpublished results). Table 8 lists the structure of the fully relaxed model and the calculated TBOD and PBOD. It should be pointed out that although the models with 250 atoms each all have BCC backbone, they are severally distorted. Table 9 shows the calculated mechanical properties in the form of elastic coefficient and mechanical parameters including the Poisson's ratio. Fig. 29 shows the bar plot of the TBOD and the PBOD for the nine HEAs. TiNbTaV has the highest and TiZrHfNb has the lowest TBOD. Detailed inspection of these data suggests that TBOD does not correlate with the number of atomic components but has more to do with the atomic size. Light atoms such as Ti or V favor the TBOD since the smaller size implied a smaller volume for the model and increase the TBOD. It also shows that PBOD can have a large variations indicating the strength of bonding between different types of atoms matters. For example Nb-Nb PBOD have relatively small contributions to the TBOD whereas Nb-Ta PBOD are relatively strong. So the data from these 12 HEAs again illustrates the merit of using TBOD to characterize the strength for a complex material. Additional modeling and data analysis are currently in progress.

Table 8 TBOD and PBOD in 9 BCC high entropy alloys (HEAs)

BCC	HEAs	Volume ($\text{\AA}^3$)	TBOD ($e/\text{\AA}^3$)
1	TiNbTaV	4161.047	0.04799

Ni-Based Superalloys

Ni-based superalloy is another class of multi-component alloys developed more than several decades ago mainly for high temperature applications (Donachie and Donachie, 2002; He *et al.*, 1994; Hong *et al.*, 2001; Fayman, 1987; Ruiz *et al.*, 1992). They all have extremely complex structures and a variety of important applications especially in power plants that need corrosion-resistant alloys at elevated temperature (Nagode *et al.*, 2011; Klueh, 2005; Fujita, 1992). It has a lot of similarities and differences with HEA or BMG. HEAs have almost equally compositions to boost the entropy whereas Ni superalloys have a lot more compositions large and small and many of them are form precipitates structural defects. Since it is Ni-based with Ni (gamma phase) as the major component, the base structure is FCC but can also be multi-phased. It contains a lot of defects, especially the precipitate phases such as γ' (Ni_3Al), γ'' (Ni_3Nb) and Cr_{23}C_6 etc. at grain boundaries, and surface of voids. It can contain elements of more than a dozen of atomic components ranging from less than 1% to over 50% with the major components from transition metals in addition to Ni. All these factors control their mechanical behavior, durability and corrosion resistance. Almost all commercially produced Ni-based superalloy are fabricated by trial and error approach and atomic-scale understanding of these complex superalloy is non-existent. This offers another opportunity to test the efficacy of using TBOD and PBOD as gene for complex materials design based on large-scale computation with tremendous economic benefit to alloy industry.

We have some preliminary results on the investigation of Ni-based superalloys. We choice commercially available alloys Inconel740 and Haynes282 as examples, each of them contain 11 different atomic components. This is shown in the Table 10. The structure of these two alloys is represented by the random solid solution model (RSSM) similar to HEA except the large difference in the atomic percentage of the constituent elements. Hence a large supercell must be used. Due to computational limitations, we choice to use an 864-atoms model in FCC lattice as shown in the ball and stick model in Fig. 30(a) and (b).

These models are fully relaxed using VASP and their electronic structure and bonding are obtained using OLCAO method. The results are summarized in Table 11 showing that Haynes282 has a slightly larger TBOD than Inconel740. On the other hand; Inconel740 has slightly larger total BO and modulus values in general. A larger Pugh's ratio (G/K) for Inconel implies it to be slightly more ductile. (Ching *et al.*, unpublished results). It will be more desirable to confirm these results when another set of random solid solution model to ascertain the degree of statistical fluctuations due to the random distribution of the atoms. On the

	Ni	Cr	Co	Al	Ti	Nb	Mo	Fe	Mn	Si	C	B	TBO	TBOD
Haynes	51.37	23.42	9.11	6.53	2.9	0	2.92	1.35	0.31	0.61	1.33	0.15	421.0233	0.04274
# Atoms	444	202	79	56	25	0	25	12	3	5	12	1		
Inconel	43.13	28.46	17.72	3.81	2.41	0.71	0.17	0.69	0.31	1.95	0.64	0	412.9632	0.04263
# Atoms	373	246	153	33	21	6	1	6	3	17	5	0		

other hand, it also demonstrate that these two commercially developed Ni-superalloys have similar desirable properties other than the differences in atomic constituents and their compositions.

From these very preliminary results for the complex Ni-based superalloys, it seems that our strategy and design for TM based metallic alloys is on the right track. The challenges are large but are not insurmountable.

Extension to Biomolecular Systems and Their Interfaces

We add this section to this chapter since the term geno originated from biology. Over the years, we used the same methods described in Section 2 to study the electronic structure and bonding in biomolecular systems including water. The first successful calculation for large biomolecules in 2003 on cyanocobalamin (vitamin B12) (Ouyang *et al.*, 2003). The ability to calculate hydrogen bonding accurately made a lot of difference (Ouyang *et al.*, 2003; Liang *et al.*, 2009, 2011; Poudel *et al.*, 2014; Adhikari *et al.*, 2014; Poudel *et al.*, 2015; Eifler *et al.*, 2016; Poudel *et al.*, 2016; Gong *et al.*, 2017; Poudel *et al.*, 2017a,c). Unlike the crystalline system or other materials represented by supercell with a definitive volume, in biomolecular systems, volume is not a useful or relevant parameter. Nevertheless, we can still use the concept to total bond order (TBO) or partial bond order (PBO) in analyzing the much more complex bonding situation involving biomolecules as will be presented in three selected examples below.

Complex Biomolecules

For complex biomolecular systems, we chose the calculation of G-quadruple DNA as an example (Poudel *et al.*, 2016) since this work encompasses the complexity of the system with solvent effect, metal ions, topology and hydrogen bonding in human telomeric G-quadruplex DNA through electronic structure calculation using DFT. 12 well-designed 3-dimensional G-quadruplex (G4-DNA) models (A1-A6, B1-B6) in different environments are constructed and their TBOs, total energies and HOMO-LUMO gaps are calculated. (Tables 12 and 13). Fig. 31 illustrate the basics of the 12 models. In the parallel structure (A models), the polarities for all strands are in the same direction, whereas in the anti-parallel type (B models), each strand has opposite orientation with respect to adjacent strands. Our study shows that the parallel strand structures are more stable in dry environment. The parallel G4-DNA (A models) has larger TBO and lower total energy than the anti-parallel one (B models) for all solvated and non-solvated models. The only exception is for the case of inner Na^+ ions with water molecules (A4 vs B4). Therefore, the parallel structures of G4-DNA are more stable than the anti-parallel structures for non-solvated and K^+ solvated ones (A4), whereas the anti-parallel structure is more stable when solvated with Na^+ (B4).

Table 12 The 12 G4-DNA models. Left column originates from the parallel 1KF1 structure, right column originates from the anti-parallel 143D structure. The environment of each pair in the row is the same

Name	Parallel G4-DNA	Name	Anti-Parallel DNA
A1	1KF1 + 21Na(b)	B1	143D + 21Na(b)
A2	1KF1 + 21Na(b) + 68H ₂ O	B2	143D + 21Na(b) + 68H ₂ O
A3	1KF1 + 18Na(b) + 3Na(c)	B3	143D + 18Na(b) + 3Na(c)
A4	1KF1 + 18Na(b) + 3Na(b) + 68H ₂ O	B4	143D + 18Na(b) + 3Na(c) + 68H ₂ O
A5	1KF1 + 18Na(b) + 3K(c)	B5	143D + 18Na(b) + 3K(c)
A6	1KF1 + 18Na(b) + 3K(c) + 68H ₂ O	B6	143D + 18Na(b) + 3K(c) + 68H ₂ O

Table 13 Calculated total energy, total bond order values and HOMO-LUMO gap of G4-DNA models

Models	Total energy (eV)	TBO (e)	HOMO-LUMO gap (eV)	Models	Total energy (eV)	TBO (e)	HOMO- LUMO gap (eV)
A1	− 4786.021	312.478	3.11	B1	− 4785.828	312.679	2.67
A2	− 5794.530	353.073	2.46	B2	− 5794.034	353.559	2.14
A3	− 4794.104	313.515	1.38	B3	− 4792.813	313.359	0.98
A4	− 5800.260	354.017	1.93	B4	− 5800.510	354.597	1.74
A5	− 4793.337	312.360	1.12	B5	− 4792.247	312.419	1.04
A6	− 5797.100	352.831	1.99	B6	− 5796.565	352.995	1.69

**Fig. 31** Structure and topology of two G-quadruplex (G4) DNA conformations. Arrows represent the direction of DNA strands from 5' to 3' end. (a) G-tetrad with alkali ion (M^+), (b) parallel type uni-molecular G4, and (c) anti-parallel basket type uni-molecular G4.

The presence of metal ions within the tetrad of the guanine channel always enhances the stability of the G4-DNA models. The parallel strand structures have larger HOMO-LUMO gaps than antiparallel structures. Partial charge calculations show that sugar and alkali ions are positively charged whereas nucleobases, PO_4 groups and water molecules are all negatively charged. Partial charges on each functional group with different sign and magnitude contribute differently to the electrostatic interactions involving G4-DNA and favor the parallel structure. Comparative study between specific pairs of different G4-DNA models shows that the Hoogsteen $O\cdots H$ and $N\cdots H$ hydrogen bonds in the guanine tetrad are significantly influenced by the presence of metal ions and water molecules, collectively affecting the structure and stability of G4-DNA. **Fig. 32** shows the Hoogsteen HB for model A4 and A6. This example is one of the most complex and challenging biomolecular systems we studied so far. Some of the details can be found in the published paper (Poudel *et al.*, 2016).

Interfaces of Biomolecules and Inorganic Crystals

This topic focuses on the interfaces between biological peptides and inorganic crystals which has attracted a lot of attention recently (Nel *et al.*, 2009; Patwardhan *et al.*, 2012; Alava *et al.*, 2013). TBOD again plays a key role as a parameter for explanation of the mechanism involved for interfacial interaction. Many materials formed in Nature always take such advantage (Munch *et al.*, 2008). Here we show a specific example of the solvated interface between a peptide with an 8 amino acid sequence (HIS-THR-GLN-ASN-MET-ARG-MET-TYR-GLU-PRO-TRP-PHE) (Sarıkaya *et al.*, 2004; Evans *et al.*, 2008) and

Fig. 32 (a) Hoogsteen hydrogen bonds (N...H, O...H) in the 2-D planar view (BLs) for Model A4 showing Na ion at the center. (b) Model A6 with K ion at the center. (c) and (d) are the side view of the (a) and (b) for model A4 and A6, respectively. The color designation for atoms are: H(green), N(blue), C(gray), O(red), P(orange), K(pink), and Na(purple).

aragonite or Nacre, a very strong crystalline calcium carbonate CaCO_3 (Brown *et al.*, 2014). Large scale computational modeling on this interface model (see Fig. 33) constructed by using AIMD and DFT calculations were carried out (Poudel *et al.*, 2017a,b,c). The calculated TBOD in this interface model show the dynamic interplay of different competing bonds in the interactions. Four amino acids HIS1, ARG6, MET7 and TRP11 in the peptide sequence have strong interfacial Ca-O bonding and O...H hydrogen bonding between aragonite and peptide. The TBOD for this interface model is $0.029 \text{ e}/(\text{\AA})^3$. Fig. 34 shows the distributions of the BO vs BL plots for bonds between three structural units: aragonite, peptide and water. It shows that the TBO between water and peptide units are much more than the sum of the TBO between other two structure units. The calculated Young's modulus is 33.37 GPa is in line with measured value for Nacre (Jackson *et al.*, 1988). This approach for interfacial study on the binding mechanism between aragonite and binding peptide in the presence of water provided a broad perspective in probing complex interactions at the biomimetic interfaces. Systematic evaluation of TBOD on models of different interfaces involving different biomolecules and inorganic crystals can rank the efficacy of peptide-surface interactions and in providing a programmable design for bio-inspired material interfaces based on computational means.

Bio-Inspired Cements

This last example we give for biomaterials is somewhat similar to the one above but with different motivations. Cement and concretes are important construction materials throughout human history. Hardened cement paste possesses extremely complex composition and structure at different length and time scale. There is an urgent need to explore novel and untraditional cementitious materials in response to increased infrastructure demand worldwide. Exploring bio-inspired cement obviously makes sense (Qian *et al.*, 2018; Phua and Røyne, 2018; Krizkova *et al.*, 2014; Ariyanti *et al.*, 2012). We have constructed a composite model between an inorganic crystal and a peptide and with water added (Ching *et al.*, 2019). It is an explicitly solvated mixture of a mineral calcium silicate hydrate (C-S-H) crystal suolunite ($\text{Ca}_2\text{Si}_2\text{O}_5(\text{OH})_2 \cdot \text{H}_2\text{O}$) (described in Section 3.3) and a specific silicon binding peptide with amino acid sequence PRO-PRO-PRO-TRP-LEU-PRO-TYR-MET-PRO-PRO-TRP-SER. The final model

Fig. 33 The structure of (a) CaCO_3 binding peptide, (b) supercell of APA interface model, and (c) supercell of APWA model. O (red), C (gray), N (blue), H (white) and Ca (green), S (yellow).

Fig. 34 Bond order vs bond length distributions for the AIMD model for bonding between pairs of structural units from left to right: aragonite-peptide (A-P), aragonite-water (A-W), and peptide-water (P-W). Each data point for a particular pair of atoms is designated with a specific symbol and color. The pie-chart represents the partial bond order in each structural unit.

structure is determined by using ab initio molecular dynamics (AIMD). The step-wise model building procedure is shown in Fig. 35. We explore the interface structure, interatomic bonding, mechanical properties and solvent effect of this bio-inspired cement. At each step in the modeling process, TBOD is used as a parameter for characterization. The importance of using AIMD in the construction of this composite model for bio-inspired cements is supported by the data shown in Table 14 for three models (AIMD0, AIMD1 and AIMD2, the final model). The solvated model has a slightly larger TBOD than the dried one. Therefore TBOD can be used in assessing the internal cohesion of bio-inspired cements and it could lead to a systematic search and design for different types of bio-inspired cements with other inorganic minerals and organic peptides.

Conclusions and Outlook

In this chapter we present many examples of using TBOD as the geno of materials. Although it started with the early calculations on ceramic crystals and glasses, it is not restricted to these classes of materials, but can be effectively extended to many complex materials.

Fig. 35 Illustration of the steps in model construction for the final SPW (AIMD-2) model.

Table 14 Comparison of the properties of 3 models in the AIMD process

	AIMD-0	AIMD-1	AIMD-2
Volume ($\text{\AA}^3$)	10816.643	10269.766	9983.951
Total energy (eV)	−5069.0485	−5074.9997	−5082.0988
Band gap (eV)	0.89	1.91	1.87
TBO (electron)	247.449	248.07020	248.4164
TBOD (electron $\text{\AA}^{-3}$)	0.02288	0.02416	0.02488

In particular, applications to the metallic materials and biomolecular systems are extremely promising. Systematic analysis of TBOD and the PBOD in relation to correlation with structures and properties provide simpler explanations on some fundamental issues of very complex systems, similar to what genomics play in biology and medicine. In a related trend, large databases on different classes of materials can be constructed purely based on computational means. TBOD and PBOD can be used as effective and important descriptors in various data mining protocols and machining learning tools far more economic than data from laboratory measurements. **Fig. 36** shows an example of applying to the MAX phases compounds. Using the data base of 664 MAX phases, half of the data is used as the training set to predict the properties of the other half. A deeper level of iterative loops using TBOD and PBOD as descriptors in artificial neural network can now predict the Poisson's ratio with over 93% of correlation coefficient ([Sakidja, private communication](#)), better than previous attempts described in the section on MAX phases. This clearly provides a strong argument to include TBOD and PBOD in machine learning algorithm for controlled improvement for specific properties ([Ball, 2019](#)). These applications are still in the early stage and I expect rapid development in the near future.

Acknowledgments

I would like to acknowledge the contributions of many collaborators including the current and past graduate students, postdoctoral fellows and visiting scientists of the Electronic Structure Group at the University of Missouri-Kansas City. Predictive Modeling of Ceramic Materials

Sarah Guerin, Syed AM Tofail, and Damien Thompson, University of Limerick, Limerick, Ireland

© 2021 Elsevier Inc. All rights reserved.

Introduction

The vital relationship between theory and experiment in materials science is both well-established and constantly evolving. Our ability to model, rationalize, and predict the properties of materials spans a variety of time scales and length scales; from the quantum realm up to long-term macroscopic behaviors. In this chapter we track the history of ceramics modeling, moving from analytical models and finite element analysis, up to modern *ab initio* methods such as Density Functional Theory (DFT) and classical Molecular Dynamics (MD) that are now computationally feasible for large and complex crystal structures due to advances in high performance computing (HPC) and software development. The chapter will start by exploring how models of fundamental ceramic properties have been developed, and then we will delve into recent developments in the predictive modeling of piezoelectric ceramics, which are widely used as sensors, actuators, and ultrasonic transducers (Jaffe, 2012).

As ceramics continue to expand their range of applications, from aerospace to advanced electronics, sophisticated theoretical and phenomenological models are needed to predict the behavior of these complex materials under realistic working conditions, and to guide rational design of advanced structures (Padture, 2016). Taking for example the testing of composite materials in the aerospace industry – requiring real engine conditions and characterization across diverse length and time scales – predictive models promise to drastically reduce the cost and effort of both the discovery and development of new materials, which could potentially provide greener, more cost-effective solutions.

Modeling Ceramics at the Macroscale

The oldest traditional use of ceramics is the porous inorganic materials used as bricks and roof tiles, the production of which remains a significant contributor to the construction industry. The infrastructural ceramics sector employs about 338,000 people in the EU and accounts for €27.8 billion in production value (CEPS, Economisti Associati and Ecorys, 2017). The widespread application of these materials is mostly due to the cheap raw materials and the standardized manufacturing processes, which follow procedures that were developed thousands of years ago. In this process clays are mixed with water to the desired plasticity, then shaped, dried and baked at $\sim 1000^{\circ}\text{C}$. Bricks and roof tiles have all the prototypical characteristics of ceramics, with high strength, durability, longevity, low reactivity, and high electrical and chemical resistance.

Despite its long history, there is still an ongoing need for modeling in the infrastructural ceramics sector, particularly when studying ceramics in historic buildings. To characterise such porous ceramics, researchers often measure a property known as sorptivity, which is associated with the principal ceramic properties listed above. Experimentally this test cannot always be performed, such as in cultural heritage sites, or even in a high-throughput automated industrial process. This has necessitated the development of analytical formulae that can accurately predict the sorptivity coefficient. For example, Pia and colleagues developed an Intermingled Fractal Units (IFU) model that reproduces pore size distributions, simulates the water absorption process, and estimates the sorptivity coefficient (Pia *et al.*, 2016b). The results of the model have been benchmarked against multiple experimental datasets and theoretical predictions (Pia *et al.*, 2016a; Pia and Sanna, 2013, 2014), illustrating the power of predictive models for designing future materials and predicting their lifespans.

Sadowski and Samborski (2003) took a different approach and developed a mesomechanical model to study porous polycrystalline ceramics under tension and compression. The model assumes the porosity of the material is distributed homogeneously inside the grains and along the grain boundaries. In their paper, two different crack initiation mechanisms are proposed and analysed for tension and compression. The proposed description of two different mechanisms of crack nucleation and propagation results in formulation of constitutive relations in order to specify differences in the material behavior under strain.

It is also important to highlight the role of predictive modeling as regards the processing of ceramics. Olevsky *et al.* (2005) present a model that describes anisotropic shrinkage during sintering in a powder compact of aligned, elongated particles by deriving the anisotropic sintering stress and the anisotropic generalized viscosity as a function of material and geometric parameters. The powder compact consists of elongated particles, which are perfectly aligned and simply packed with elliptical pores between the particles. Their model considers mass transport by grain boundary diffusion and surface diffusion. Shrinkage rates are calculated for a variety of geometries and are compared to kinetic Monte Carlo simulations.

The high strength of ceramics makes them useful in the development of reduced-weight steel armors for high-speed military vehicles. Forquin *et al.* (2003) describe a bilayered geometry, with the ceramic front end dampening any projectile and spreading out the energy of impact. They modeled silicon carbide ceramics to determine the root causes of damage and failure and developed an anisotropic damage model to rationalize the experimentally observed failure scenarios. Numerical simulations substantiate the hypothesis of failure caused by the tensile stresses induced by roughness defects, and match observations from experiments. Wang and Li (2015) similarly examined the failure and fracture mechanisms of ceramics under dynamic loading, specifically alumina ceramics in composite armor. In

this study, a pressure bar technique combined with high speed photography was used to directly observe the dynamic macro-cracking and fragmentation process in alumina and to characterise the stress and strain histories. An experimentally validated 3D finite element model of the full-scale test was developed to predict the stress distribution and damage evolution in alumina. It was found that the damage evolution is determined by the multiaxial stress state, the substantial localized tensile stress concentration, and the stress direction. The cracking process leads to longitudinal axial splitting failure on the surface and internal diagonal damage bands. The dynamic failure process in alumina is dominated by both the intergranular and transgranular fracture mechanisms.

Numerical simulation methods such as finite element (FE) modeling have been extensively used to predict the stress distribution in ceramics subjected to dynamic loads, and investigate the damage evolution that it is usually difficult to observe experimentally due to the instantaneous nature at high rates. For accurate numerical simulation, various constitutive models have been developed to quantify the mechanical response of ceramics under different loading rates, such as mixed-mode cohesive laws and the Johnson–Holmquist material model with damage (JH-2). The JH-2 model has been widely accepted to simulate the mechanical behavior of damaged brittle materials subjected to high pressures, large strain, and high strain rates. However, a major limitation of the methods presented in this section is that they all require prior knowledge of the physical properties of the material. Hence, while they are invaluable for testing how to incorporate known materials in new applications and in a variety of environments, they cannot predict material properties, or screen for new ceramic materials. For this, we rely on molecular modeling, as outlined in detail in the following section.

Modeling Ceramics at the Nanoscale

Atomic-scale investigations continue to highlight how a nanoscale understanding of physical phenomena is necessary to enhance macroscopic material properties (Guerin *et al.*, 2019b). In this section the basic concepts and principles of the quantum mechanical modeling technique density functional theory (DFT) are introduced. The section outlines the physics of DFT and describes how DFT is used to predict the physical properties of ceramics. At its core, DFT is an electronic structure calculation that allows highly accurate prediction of a plethora of properties from an optimized theoretical structure at 0 Kelvin, including but not limited to: atomic charges, density of states, band gaps, binding energies, dielectric and elastic properties, lattice vibrations and phonons. Thermal effects and weak dispersion effects are now also being routinely incorporated into DFT models, which increases their relevance for ceramics modeling. DFT can complement classical molecular dynamics (MD) simulations, which essentially treat interacting atoms as Newtonian spheres connected by springs and so can treat millions of atoms for microsecond timescales beyond the reach of DFT calculations.

What is Density Functional Theory?

For single electron systems (2D potential well, hydrogenic atom) it is possible to obtain an exact solution to the Schrodinger equation (Pertsch, 1990). However, for any system more complicated than this it is impossible to precisely solve the Schrödinger equation and obtain a mathematical description of the system, i.e., the wave function, which is squared to generate the electron density. Density functional theory (DFT) provides an approximate solution to the many-body Schrodinger equation, which gives the ground state properties of the system.

The term DFT comes from the fact that the functional used in DFT calculations is the electron density, which is itself a function of space and time (mathematically, a functional takes a function and gives a resulting scalar value). The Hohenberg–Kohn (Hohenberg and Kohn, 1964) theorem tells us that the total ground state energy of a many-electron system is a functional of the density (shown for glycine in Fig. 1). The total energy of the system is written in terms of several individual energy contributions, each of which is a functional of the charge density: ion–electron potential energy; ion–ion potential energy; electron–electron energy; kinetic energy; exchange–correlation energy.

The most computationally challenging energy contributions are the kinetic energy and the exchange–correlation energy. The kinetic energy is calculated using the Kohn–Sham orbitals that map the system of interacting electrons on to a system of non-interacting electrons moving in an effective potential. The exchange–correlation energy accounts for the exchange interaction due to repulsion between electrons with parallel spins, and the correlation interaction, which is the correlated motion between electrons of anti-parallel spins due to their mutual Coulombic repulsion. Exchange–correlation effects in ceramics are often treated via the Perdew, Burke, and Ernzerhof (PBE) (Perdew *et al.*, 1992) implementation of the generalized gradient approximation (GGA) (Perdew *et al.*, 1996). GGA builds on what is known as the local density approximation (LDA), by considering both the local electron density and its gradient, as the electron density can vary rapidly over a small region of space.

Predicting Material Properties

The general methodologies outlined in the following sections are detailed as for the DFT software VASP (Vienna ab initio simulation package) (Hafner, 2007), which uses plane wave basis sets (Kresse and Furthmüller, 1996), and the projector augmented-wave (PAW) method (Kresse and Joubert, 1999) to solve the electronic structure of periodic crystalline materials. However, there are multiple

Fig. 1 The unit cell of the biomineral hydroxyapatite (HA), discussed in the following sections as a novel polycrystalline ceramic material, showing the positions of the calcium and phosphite ions (calcium in turquoise, phosphorous in lilac, oxygen in red). DFT allows us to predict the material properties, and rationalize the behavior of crystalline ceramics, starting with the unit cell (visualized using VESTA. (Momma and Izumi, 2011)).

flavors of DFT available in widely used software packages such as Quantum Espresso (Giannozzi *et al.*, 2009), cp2k (Hutter *et al.*, 2014), Gaussian (Frisch *et al.*, 2009), and ABINIT (Gonze *et al.*, 2009) which span from molecules to crystals to interfaces. Modern developments in DFT include hybrid functionals, advanced dispersion and thermal corrections; interested readers are directed to the following works: Chai and Head-Gordon (2008), Marsman *et al.* (2008), Grimme *et al.* (2010), Marom *et al.* (2013), and Reilly and Tkatchenko (2014).

Geometry Optimization

The first step in DFT ceramics modeling is to take the experimental structure of interest and allow its unit cell parameters to relax in order to obtain ideal ground state geometry. This structure could be a crystal unit cell for polycrystalline ceramics, a bulk ceramic interacting with a molecular coating, or another bulk material. Structures can be generated from experimental data, for example solved X-ray structures hosted at the Cambridge Crystallographic Data Centre (CCDC).

Structures are generally optimized using the conjugate gradient algorithm. For a periodic system, integrals in real space over the infinitely extended system are replaced by integrals over the finite first Brillouin zone in reciprocal space, in accordance with Bloch's theorem. These integrals are solved at a finite number of points in the Brillouin zone, called the k -point mesh, or grid. For the highest accuracy, a dense k -point grid should be used for geometry optimizations; and a high plane wave energy cut-off (all plane waves with a kinetic energy less than this are included in the basis set). Γ -centered k -point grids are generally recommended for non-centrosymmetric unit cells. Values should be selected after energy convergence tests with respect to N (where N = number of subdivisions of the reciprocal lattice vector), and plane wave cut off energy. Minimum converged values should be chosen to balance calculation accuracy with computational expense.

Case Study: Calculation of Elastic Constants

One of the most useful properties of ceramics is their mechanical strength, with high hardness and elastic moduli. For piezoelectric and ferroelectric ceramics, discussed in the next section, the elastic stiffness constants c_{kij} are required to calculate the piezoelectric strain constants d_{ik} (Ikeda, 1996). The elastic compliance can easily be derived from the stiffness and measured using impedance spectroscopy, as can the Young's modulus.

The elastic constants are calculated in the form of the stiffness tensor, C , presented as a 6×6 matrix (Eq. (1)). VASP outputs this tensor in Voigt notation in kB, so some post-processing is required to produce C in matrix notation in GPa.

$$C = \begin{pmatrix} c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\ c_{21} & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\ c_{31} & c_{32} & c_{33} & c_{34} & c_{35} & c_{36} \\ c_{41} & c_{42} & c_{43} & c_{44} & c_{45} & c_{46} \\ c_{51} & c_{52} & c_{53} & c_{54} & c_{55} & c_{56} \\ c_{61} & c_{62} & c_{63} & c_{64} & c_{65} & c_{66} \end{pmatrix} \quad (1)$$

The number of non-zero elements in the elastic matrix will vary according to the symmetry of the system being studied. For more information on these constants, their matrix representations and their units, readers are directed to Nye (1985). Two

methods are described below to calculate the elastic constants of ceramics; one for relatively small systems, and one for systems with a unit cell greater than approximately 250 atoms.

Finite differences

A finite difference method is the most efficient way to calculate the elastic stiffness tensor, with every atom in the unit cell displaced along each Cartesian axis by ± 0.01 Å. Generally a low density Γ -centered k -point grid can be used – multiple reports (Guerin *et al.*, 2019a, 2018b) show the negligible dependence of predicted elastic constants on the number of k -points used, once $N > 1$. If computationally feasible via HPC, a high plane wave energy cut-off ≥ 1000 eV allows the stress tensor to fully converge if there are oxygen and nitrogen atoms in the system (Tulip and Clark, 2004). Elastic moduli can be derived from the stiffness matrix components. For crystalline materials of known dimensions the approximations of Nye (1985) can be used, otherwise Voigt–Reuss approximations (Voigt, 1928; Reuss, 1929) are recommended.

Strain controlled calculations

The computational expense of a finite difference calculation scales very rapidly with increasing number of atoms in the unit cell. This is because more atoms mean more degrees of freedom, i.e., more atomic displacements need to be carried out. For larger ceramic unit cells (approx. 250 atoms at time of writing) it is computationally prudent to use single point energy calculations, following the more traditional method of applying individual volume conserving strains to the system and measuring the corresponding stress tensor (Guerin *et al.*, 2018a). As conjugate gradient relaxations can be restarted from checkpoint files, these calculations are not limited by HPC restrictions on individual runs and individual elastic constants of larger systems can be calculated.

Along with elastic properties, Petrov *et al.* (2017) used experimentally validated DFT calculations to study ion mobility in layered perovskite-like compounds. They combined DFT with impedance spectroscopy and classical molecular dynamics simulations to understand, rationalize and quantify the phenomenon across time and length scales. Using DFT, the group calculated the charges of atoms in the crystal structure and fed this into MD simulations of sodium mobility in the temperature range of 523–923K. Based on these calculations, the dependence of the diffusion coefficients of sodium atoms on temperature was studied. The mobility of sodium ions in NaLaTiO₄ is demonstrated to be higher in certain compounds due to an increase in ionic character of the chemical bonds. This study demonstrates well how to use and combine DFT and MD to study time dependent and temperature dependent phenomena. This method can also be seen in the work of Kroll (2005), who investigated the structures, energies, and elastic properties of some polymer-derived nitride ceramics. These model structures ranged in size from 104 to 448 atoms and were generated by an empirical network algorithm prior to DFT and MD calculations due to the paucity of available crystal structures, even as non-oxide ceramics were gaining attention due of their covalent bonding providing mechanical reliability and high-temperature stability. Synthesized from polymers, all nitride ceramics remain amorphous at least up to 1000°C. Even at higher temperatures much of the material is featureless and amorphous, with some materials retaining a predominantly amorphous structure at 2000°C.

An interesting use of DFT calculations in biocompatible ceramics modeling can be found in the work of Haverty *et al.* (2005). Hydroxyapatite (HA) is a leading biocompatible material extensively used for bone implants as a porous ceramic graft and as a bioactive coating (Shikinami and Okuno, 2001, 1999). Electrical characteristics of HA can be employed in implantable devices for real-time in vivo pressure sensor applications such as in knee or hip prosthetics (Tofail *et al.*, 2015). In this work, DFT calculations combined with Rietveld analysis (a technique used to extract crystal characteristics from Powder XRD measurements) was used to challenge the proposed crystal structure of HA. By studying the structure and energetics of HA, the previously proposed P6₃/m and P6₃ hexagonal structural models were found to be energetically unfavorable when compared to both the previously proposed P2₁/b symmetry and a newly proposed monoclinic P2₁ structural model. A detailed analysis of the symmetry restrictions and inconsistencies between the reported physical properties, such as diffraction and birefringence, with hexagonal symmetry questioned the validity of the previous models. Rietveld analysis carried out on a synthetic sample, reported to be predominantly hexagonal at room temperature, showed that the diffraction pattern of this material can be interpreted as a mixed monoclinic phase, 23% monoclinic P2₁/b and 77% monoclinic P2₁. This interpretation reconciled many anomalies in reported experimental observations.

DFT for Piezoelectric Ceramics

Piezoelectric ceramics generate a surface charge that is proportional to an applied force, and conversely strain in the presence of an electric field. The most widely used piezoelectric ceramic is Lead Zirconium Titanate (PZT) (Chen *et al.*, 2010, Lobl *et al.*, 1999), followed by its lead-free alternative Barium Titanate (Berlincourt and Jaffe, 1958, Gao *et al.*, 2011). In the past decade, research has intensified to find high-performance lead-free piezoceramics (Shrout and Zhang, 2007), due to stricter environmental regulations, and also due to the growing field of implantable piezoceramics for medical device applications. Molecular modeling is an invaluable tool to screen for piezoceramic compositions that could challenge PZT as regards high piezoelectric constants, low permittivity, high Curie temperature, and high electromechanical efficiency. However, there is also a wide variety of applications for piezoceramics with more modest piezoelectric constants (Damjanovic, 1998), particularly organic piezoceramics (Wu *et al.*, 2016, You *et al.*, 2017). For example, hydroxyapatite, as mentioned in the previous section, is a biocompatible piezoceramic when poled under a high electric field (Gandhi *et al.*, 2014, Tofail *et al.*, 2009). The selective adsorption of proteins on polarized domains indicate the potential for real-time biosensing applications of HA (Korostynska *et al.*, 2013).

Calculation of piezoelectric charge tensor

Piezoelectric charge constants, e_{ij} , can be calculated using density functional perturbation theory (DFPT) (Wu *et al.*, 2005). Similar considerations for k -point grids and plane wave cut off values should be made as for elastic constant calculations. The magnitudes of piezoelectric constants calculated with a single k -point are generally not physically realistic, nor consistent with crystal symmetries. Using the piezoelectric charge coefficients, e_{ij} , which are calculated directly by VASP, and the elastic stiffness constants, c_{kj} , we can calculate the more useful piezoelectric strain coefficient, d_{ik} , using the relationship

$$d_{ik} = e_{ij} / c_{kj} \quad (2)$$

Currently, VASP only supports calculation of the ionic contribution to the elastic stiffness constants using DFPT, and so cannot be used to derive the full elastic stiffness tensor in the same calculation. Typical deviations between finite difference calculations and DFPT range from 0% to 15% (Guerin *et al.*, 2017) with the maximum deviation providing an estimate of the theoretical error in the predictions.

Derivation of voltage constants

DFPT calculations can also predict the static dielectric tensor of the ceramic being studied (Gonze and Lee, 1997). Using the dielectric tensor, we can extract the final piezoelectric constant: the voltage constant, g_{ik} . This is an important figure of merit (FoM) for energy harvesting applications, and in motion and pressure sensing. To obtain these g_{ik} values we can divide the corresponding piezoelectric strain constant, d_{ik} , by the relevant dielectric constant ϵ_{ii} , as shown in Eq. (3). These constants are measured in V m/N.

$$g_{ik} = d_{ik} / \epsilon_{ii} \epsilon_0 \quad (3)$$

Future of Ceramics Modeling

The range of applications for ceramic materials continues to expand and diversify. As it does, modeling needs to develop alongside it – in particular, accurate high-throughput screening of structures and properties is required, to provide atomic-scale insight into macroscopic phenomena. We are already beginning to see the emergence of machine learning in ceramics modeling (de Jong *et al.*, 2015), which will become even more exciting and influential as machine learning and artificial intelligence become more prominent in both research and industry. As exemplified by the work reviewed in this work, ceramic composites and bio-compatible ceramics are very active areas of research, and simulation-guided experiments will be crucial to increase the variety of available compositions and structures and so accelerate applications for these materials. An ongoing challenge for all computational models, particularly DFT, is to accurately simulate the properties of ceramic materials in presence of dopants (Alay-e-Abbas *et al.*, 2019; Mathew *et al.*, 2018), additives (Barauskas *et al.*, 2018; Chen *et al.*, 2018) and fillers (Agrawal and Satapathy, 2015; Song *et al.*, 2019), the use of which is common practice and hugely impacts the final application. Continuous improvements and expansion of computational modeling methods such as polarizable force fields and combined DFT/MD models, coupled with advances in HPC and data processing, should soon provide researchers with truly predictive computational tools to steer and speed discovery and development of ceramic materials for an ever expanding range of technology applications.

Molecular Dynamics Simulations of Glass Structure

Mattias Edén, Stockholm University, Stockholm, Sweden

© 2021 Elsevier Inc. All rights reserved.

Introduction

The utilization of atomistic molecular dynamics (MD) simulations to model glass structures has increased markedly over the past two decades, where it nowadays has emerged as a valuable complement to experimental techniques, such as X-ray/neutron diffraction, and infrared (IR), Raman, X-ray absorption (XAS), and nuclear magnetic resonance (NMR) spectroscopies. Furthermore, an MD-generated glass model comprises a wealth of structural information, much of which is currently not experimentally attainable even for simple binary glasses. This introduction to, and overview of, applications of atomistic MD simulations to probe glass structure focusses on *oxide-based* glasses, which are targeted by an overwhelming majority of all literature reports on non-metallic glasses. Moreover, this review solely covers structural aspects of glasses, while another important branch concerns the modeling of physical, mechanical, and chemical properties for unveiling composition–structure–property correlations to assist a rational design for tuning the glass properties.

This paper is organized as follows: We start by accounting for the basic structural features of oxide-based glasses (Section “Introduction to Oxide-Based Glass Structures”), while Section “Salient Features of Atomistic MD Simulations” provides a gentle introduction to atomistic MD simulations, where we outline the principles of *ab initio* as well as classical MD simulations. Section “Melt-Quench Simulations” describes the modeling of the melt-quench process, which is the prevailing procedure to prepare oxide-based glasses, and which is also emulated by the computer simulations. Section “Force Fields” describes how interatomic interactions are modeled using force fields in classical MD simulations, where we review various common force field parameterizations, including those that account for ion polarizations effects. Next, Section “Evaluation of Short-Range Structural Parameters” illustrates how short-range (local) structural features may be assessed from the glass models, whereas Section “Modeling of Various Glass Systems” concludes by reviewing several key structural problems addressed in recent MD simulation reports of various glass systems, encompassing modified silicate, phosphosilicate, and aluminosilicate glasses, as well as borate and borosilicate glasses.

Introduction to Oxide-Based Glass Structures

Glass Building Blocks

Oxide-based glasses are built from *network formers* (F), the most common being B, Si, Al, and P, which are interlinked by *bridging* oxygen (BO) atoms via covalent $-O-$ linkages to form polymeric networks (Greaves and Sen, 2007; Edén, 2012). The network-building blocks are FO_p polyhedra, where tetrahedra ($p=4$) prevails, such as for Si (SiO_4), and notably P (PO_4), as illustrated by the network fragment of an MD-generated $Na_2O-CaO-B_2O_3-SiO_2-P_2O_5$ glass model in Fig. 1. While AlO_4 groups normally also dominate the networks of aluminate and aluminosilicate glasses, higher-coordination AlO_5 and AlO_6 polyhedra are frequently encountered across certain glass composition domains (see Section “Aluminosilicates”), particularly in aluminophosphate glasses where the strong propensity of P to remain in tetrahedral coordination leads to the formation of AlO_5 and AlO_6 moieties. Similarly, besides BO_4 tetrahedra, the small B atom commonly forms planar BO_3 units in B-bearing glasses [Fig. 1(a)], whereas the structure of vitreous B_2O_3 consists entirely of BO_3 moieties, most of which are condensed further into “boroxol” rings (B_2O_6) (Greaves and Sen, 2007; Edén, 2012). The coordination number Z_E of a species E will onwards be specified by appending the element symbol by a superscript: $E^{[p]}$.

Electropositive cations of alkali (M^+) and alkaline earth (M^{2+}) metals are termed *glass-network modifiers* because they depolymerize the networks by converting BO atoms into *non-bridging* oxygen (NBO; O^-) ions (Edén, 2012); see Fig. 1. This alters the physical and chemical properties of the glass and its corresponding melt, with implication for materials design as well as for geological processes, such as the flow properties (e.g., viscosity) of magma. The positive modifier ions balance primarily the negatively charged NBO ions, at which they locate through predominantly electrostatic $M^{z+} \cdots O^-$ interactions. Nonetheless, $M-BO$ contacts also occur, such that a non-negligible number of BO atoms contribute to the MO_p polyhedra. The glass-network modifier ions (M^{z+}) are normally larger than their F^{z+} counterparts and therefore feature higher coordination numbers, as in crystalline phases. For example, the similar-sized Na^+ and Ca^{2+} ions are typically surrounded by 5–7 O species [see Fig. 1(b)], whereas larger cations adopt six- to nine-fold coordination and the small Mg^{2+} ion may even participate in the glass network as MgO_4 groups (Edén, 2012).

Owing to the prevalence of tetrahedral coordination of Si and P, their coordination numbers will not be indicated explicitly. Rather, the symbols Q^n_i and Q^n_p will be employed for an SiO_4 and PO_4 tetrahedron with n BO atoms (and consequently $4 - n$ NBO ions), respectively (Engelhardt and Michel, 1987); see Fig. 2. Likewise, $Al^{[4]}$ species are denoted Q^n_{Al} , although generally Q^4_{Al} groups prevails in Al-bearing glasses (see Section “Aluminosilicates”). Here “Q” stands for “quaternary” to stress the fourfold coordination of Si, P, and Al. The Q^n notation is frequently encountered in the literature on silicate (and phosphate) glasses, where the fractional

Note that only the BO/NBO and the network-forming (Si, B, P) atoms are displayed. (b) Structural motif around a NaO_5 polyhedron, indicating its coordination to four NBO and one BO species and their respective bonds to Si and P. The structure fragment in (a) is reproduced with permission from The American Chemical Society from [Yu, Y., Stevansson, B., Edén, M., 2017. Medium-range structural organization of phosphorus-bearing borosilicate glasses revealed by advanced solid-state NMR experiments and MD simulations: Consequences of B/Si substitutions. *J. Phys. Chem. B* 121, 9737–9752].

populations $\{x_{\text{Si}}^0, x_{\text{Si}}^1, x_{\text{Si}}^2, x_{\text{Si}}^3, x_{\text{Si}}^4\}$ of $\{Q_{\text{Si}}^0, Q_{\text{Si}}^1, Q_{\text{Si}}^2, Q_{\text{Si}}^3, Q_{\text{Si}}^4\}$ silicate groups directly relates to the NBO content of the glass and the polymerization degree of the silicate network and thereby to its average topology. A measure of the average glass network topology is given by the silicate *network connectivity* (Engelhardt and Michel, 1987; Edén, 2011), corresponding to the *average* number of BO atoms per SiO_4 group ($\bar{N}_{\text{BO}}^{\text{Si}}$) and given by:

$$\bar{N}_{\text{BO}}^{\text{Si}} \equiv \bar{n} = \sum_{n=0}^4 n x_{\text{Si}}^n, \quad (1)$$

with the fractional populations obeying the normalization $\sum_n x_{\text{Si}}^n = 1$.

The description of phosphate glasses is analogous, where a weighted average involving the set of fractional populations $\{x_{\text{P}}^n\}$ of $\{Q_{\text{P}}^n\}$ groups is linked to the average number of BO atoms per PO_4 group ($\bar{N}_{\text{BO}}^{\text{P}}$). The only essential difference to the silicate case is the restriction $n \leq 3$ of the Q_{P}^n groups due to the $\text{P}=\text{O}$ bond of each PO_4 moiety.

Structural Order

Notwithstanding that glasses are amorphous phases and thereby lack “long-range” order in the sense that no periodicity exists beyond ≈ 0.5 nm from a given spatial coordinate—the presence of well-defined FO_p polyhedra that form the glass network along with its associated MO_p moieties—implies that an oxide-based glass possesses *short-range* order, just as its crystalline phase of similar stoichiometry (Zachariasen, 1932; Engelhardt and Michel, 1987). However, in contrast with the latter, a “geometrical” disorder is introduced in the glass structure due to distributions of $\text{F}-\text{O}-\text{F}'$ bond angles and $\text{F}-\text{O}$ distances, which in turn dictates the precise positions of the network modifiers. Moreover, in glass networks involving either more than one network-former species ($\text{F}, \text{F}', \text{F}'', \dots$), or multiple coordination numbers (e.g., $\text{Al}^{[4]}, \text{Al}^{[5]}, \text{Al}^{[6]}$), a “chemical” disorder results from distributions of $\text{F}-\text{O}-\text{F}'$ bonding patterns, although they are partially constrained by preferences for certain $\text{F}-\text{O}-\text{F}'$ bonding scenarios, such as the favoring of $\text{Al}-\text{O}-\text{P}$ linkages but the avoidance of $\text{Al}^{[4]}-\text{O}-\text{Al}^{[4]}$ bridges; the latter feature is known as the “Loewenstein Al avoidance” rule (Loewenstein, 1954) and stems from the negative charge of the $[\text{AlO}_4]^-$ tetrahedron (although Loewenstein himself emphasized spatial/geometrical constraints rather than charge arguments). Hence, the disordered and thereby less dense glass structure readily admits exceptions to bonding “rules” that may be much stricter in analogous crystalline phases, such as the Loewenstein rule in aluminosilicates (e.g., zeolites) (Engelhardt and Michel, 1987).

The presence of constraints on $\text{F}-\text{O}-\text{F}'$ bonding preferences is one reason why oxide-based glasses often possess *medium-range order* over a few hundred picometers (0.3–0.5 nm). Unfortunately, the experimental probing of this particular range is challenging: The limitations of diffraction/scattering methods are obvious because they require long-range structural order, while the most widely exploited spectroscopic techniques, i.e., IR and Raman spectroscopy, are limited by poor spectral resolution and may in general only inform about short-range ($\lesssim 0.3$ nm) features. Although routine solid-state NMR experimentation suffers from similar problems, advanced NMR techniques may reveal some features of the glass structure across the 0.3–1.0 nm scale (Edén, 2012), such as preferential $\text{F}-\text{O}-\text{F}'$ bonding patterns or the nature of the spatial distribution of a few network modifier species (e.g., Na and Li). Yet, application of such experimentation is non-standard and comparatively sparse. Here atomistic MD

Fig. 2 Illustration of the Q^n nomenclature for tetrahedrally coordinated network formers, here assuming SiO_4 groups. Only oxygen atoms are indicated, with bridging and non-bridging species depicted in black and blue color, respectively. (a) An isolated Q^0_{Si} (orthosilicate) tetrahedron. (b) A Q^2_{Si} unit linked to two Q^1_{Si} terminal tetrahedra. (c, d) A central (c) Q^3_{Si} and (d) Q^4_{Si} tetrahedron connected to Q^1_{Si} groups.

simulations offer great opportunities for gaining complementary structural insight to that accessible from experiments. MD simulations may provide short-range structural parameters that are in principle attainable experimentally but that in practice remain unreported, as well as insight into some medium-range glass structural features that are exceedingly difficult to obtain by other means.

Salient Features of Atomistic MD Simulations

Classical and *Ab Initio* Calculations

Notwithstanding that the $F\text{--O}$ bonds (e.g., Si--O and B--O) have a significant covalent character and oxide-based glasses form polymeric networks, glass structures are almost without exceptions modeled *atomistically*, meaning that the dynamic control is at the atomic level rather than considering larger molecular units, such as the SiO_4 or AlO_6 moieties. An obvious advantage with this approach is its lack of bias concerning the chemical bonds. Moreover, to what extent a minor species is present (such as AlO_6 groups in aluminosilicate glasses), is *a priori* unknown and is merely the task of the simulation to predict. Atomistic MD simulations involve a repositioning of atoms until an “equilibrium structure” is reached, within the practical limitations of

actually reaching such an equilibrium state, where we also note that glasses are thermodynamically metastable phases. Strictly, “equilibrium” is here taken to mean that the atom ensemble has reached a sufficiently low potential energy (concerning all atom pairs as well as any larger atom aggregates) such that no significant changes are observed in the structure as time proceeds.

As implied by its name, “modeling” by atomistic MD simulations yields an energy-minimized structure that represents a *model* of the real physical structure. The accuracy of this model depends on the assumptions underlying its production, i.e., how precisely the forces acting on each atom reflect the “real” ones. Broadly, there are two options for reaching the MD-derived model:

- (1) To perform *ab initio* MD (AIMD), i.e., “first principle” calculations, which is tantamount to solving the Schrödinger equation for the atom ensemble and thereby defining the position of each nucleus and its surrounding electrons. While representing the most accurate modeling, such computations become extremely time and computer-memory consuming albeit some approximations are made, such as those of Car–Parrinello MD (CPMD) simulations, where the electron dynamics is handled by density functional theory (DFT) at each time step (Car and Parrinello, 1985). Current AIMD simulations are restricted to handling a few hundred atoms over a period of ≈ 100 ps. These limitations of AIMD calculations lead to obstacles such as obtaining a sufficiently long time scale for reaching the energy minimum, and uncertainties in the populations of minor species in the structure (see Section “Atom Ensembles”).
- (2) To ignore the electron dynamics and assume that classical mechanics provides a sufficiently accurate representation of the equation of motion of each atom. The latter is dictated by *force fields*, which are also referred to as *interatomic potentials*. Below we will use these two synonymous terms interchangeably. The potentials represent functionals that provide the interatomic energy, as discussed in more detail in Section “Force Fields.” By omitting the electrons from the dynamic picture, the *classical* MD simulations rely on the Newtonian equations of motion (Allen and Tildesley, 1987). Yet, this permits handling atom ensembles comprising 10^3 – 10^5 atoms, as well as using timescales of hundreds of ps and beyond. However, the results depend critically on the accuracy of the force field functional and its precise parameters.

Atom Ensembles

Regardless of whether AIMD or classical mechanics are employed, the physical constraints of the atomistic MD simulations may be selected to involve *NPT*, *NVT*, or *NVE* ensembles, where each letter specifies a parameter that is fixed at any given time-point during the simulation. Here, *N* corresponds to the number of atoms, whereas *T*, *P*, *V*, and *E* represent the temperature, pressure, volume, and (net) energy of the atom ensemble, respectively. Consequently, an *NVT* (*NPT*) ensemble requires that the volume (pressure) is kept constant at each time-point of the simulation stage, whereas the pressure (volume) is allowed to vary freely. *NPT* calculations are normally preferred over their *NVT* counterparts. Hence, a force field that reproduces the experimental glass density under *NPT* conditions must be considered as the most favorable one relative to other options. Yet, such scenarios are rare, thereby in practice rendering *NVT* simulations that employ the experimental glass density preferable for obtaining an accurate glass model of a given chemical composition.

Atomistic MD simulations employ a (cubic) box with periodic boundary conditions, meaning that once an atom traverses one boundary face of the box (e.g., at the top) during the course of the simulation, it will reappear at the opposite face (at the bottom). While such periodic boundary conditions artificially expand the “box size” and efficiently avoids undesirable “surface” effects, false periodicities (i.e., “ordering” effects) may be introduced for (too) small boxes. The choice of the side length of the cubic box (which is usually a few nanometers) is dictated mainly by the total number of atoms, which in turn must be selected by considering the glass composition to be sufficiently large to provide adequate statistics about the least abundant species in the final glass model. For *NVT* simulations, the box size is selected by the constraint that the mass density of the atom ensemble must match the experimental counterpart at all times throughout the simulation. Fig. 3 depicts a glass model generated in a box.

Atomistic MD simulations are bound to give “discretization” effects of the structural-parameter statistics, such as of the various populations of $F^{[p]}$ and $M^{[p]}$ species, as well as the F – O – F' bonding constellations in the glass model. While the loss in accuracy due to limited statistics may, for instance, be significant for the comparably rare $Al^{[6]}$ species in alkali/alkaline-earth based aluminosilicate glasses with low Al contents (Section “Aluminosilicates”), they are usually insignificant for the most abundant species, such as the BO and NBO populations. Consequently, classical simulations of (say) binary Na_2O – SiO_2 glasses with comparable Na_2O and SiO_2 contents only require 2000–3000 atoms to give precise assessments of the distributions of the $\{Q_{Si}^n\}$ and $\{Na^{[p]}\}$ species, as well as many other structural parameters, such as the Si–O–Si bond-angle distributions (Section “Evaluation of Short-Range Structural Parameters”). Yet, typically 5000–10,000 atoms are required for multi-component glasses, or if precise information is required about a species present in minute amounts in the modeled structure. Hence, the choice of the total number of atoms must be made as a compromise between the largest possible atom ensemble for improving the statistics on the evaluated structural parameters, while keeping the system sufficiently small to avoid excessively time-consuming computations (where obviously also the precise choice of force-field becomes important, for which similar compromises between accuracy and computational speed must be made; see Section “Force Fields”).

Melt-Quench Simulations

The Procedure

Glass structures are modeled by emulating the traditional experimental melt-quench process for glass production, where a melt is gradually cooled until the system “freezes” and transforms into a glass. The simulation starts from an ensemble of atoms placed

Fig. 3 Illustration of a small ensemble of ≈ 500 atoms from a $\text{Na}_2\text{O}-\text{SiO}_2-\text{P}_2\text{O}_5$ glass model generated by a melt-quench procedure.

randomly (but subject to a minimum distance to any neighbor) in a box with periodic boundary conditions. The system is then equilibrated for ~ 100 ps at high temperature (typically, $3000\text{--}6000^\circ\text{C}$) to ensure freely moving atoms in a liquid state (melt) and for removing any “memory effects” of the atom ensemble.

As for all other parts of the (classical) MD simulation, the atom dynamics during the initial equilibration stage is dictated by the force field and involves integrating the equations of motion (Newton’s second law) (Allen and Tildesley, 1987). This leads to an updated spatial coordinate of each atom at each new time-point, where the time progression of the atom ensemble—which is often referred to as the trajectory—depends on the previous set of atom coordinates and the interatomic forces at the previous time-point; see Allen and Tildesley (1987) for details about the practical integration of the Newtonian dynamics. Depending on the precise choice of force field, the MD simulation trajectory is typically sampled in small time steps, where ≈ 0.2 fs and ≈ 1 fs are typical for force fields involving shell and rigid-ion models, respectively (see Section “Force Fields”). In contrast, a ≈ 0.1 fs step is required for AIMD computations that consider the dynamics of the nuclei as well as electrons.

Once the equilibration of the atom ensemble representing a high-temperature “melt” is completed, the system is gradually cooled to a “low” temperature ($\sim 20^\circ\text{C}$) by a cooling rate (q_c ; in units of K s^{-1}). The melt cooling may be implemented either as an essentially “continuous” (yet, step-wise by q_c) temperature reduction, or by invoking “equilibration stages” during the procedure. The temperature is in practice controlled by a “thermostat” procedure, the most common being those of Berendsen, and Nosé-Hoover (Allen and Tildesley, 1987). Further improved thermostats were devised by gently adding stochastic forces to ensure that the kinetic energy distribution is sampled efficiently and for improving ergodicity (Bussi *et al.*, 2007; Samoletov *et al.*, 2007).

Once the final temperature is reached, the MD calculation ends with a final equilibration stage that spans tens and hundreds of ps for AIMD and classical MD simulations, respectively. In classical and AIMD simulations, the last 100–200 ps and 10–20 ps of the equilibration interval, respectively, is employed for deriving the average structural parameters of the glass model; this period is in MD-jargon language referred to as the “production run.” To improve statistics and enabling the assessment of uncertainties of the modeled structural parameters, the entire melt-quench process should be repeated in a few independent simulations (at least three), each starting from randomly distributed atoms at high temperature.

There are several open-source MD simulation codes for implementing melt-quench simulations, including options for efficiently distributing the calculations among multiple computer processors (“parallelization”): For classical MD simulations, the most commonly utilized simulation platforms are DLPOLY (Smith and Forester, 1996; Todorov *et al.*, 2006) and LAMMPS (Plimpton, 1995), whereas the QUANTUM ESPRESSO (Giannozzi *et al.*, 2009) package is popular for AIMD computations.

The Cooling Rate

Cooling rates in current literature that involve classical MD simulations are typically $5\text{--}10\text{ K ps}^{-1}$, whereas modeling work reported 2–3 decades ago merely utilized $20\text{--}100\text{ K ps}^{-1}$. Although this nearly tenfold reduction in q_c is by no means insignificant for suppressing some “exotic” structural species that otherwise arise as simulation artifacts (e.g., $\text{Si}^{[5]}$ and $\text{Al}^{[3]}$ species in silicate and aluminosilicate glass models), the $\approx 10^{10}$ orders-of-magnitude faster melt-quenching employed in atomistic MD simulations relative to the $100\text{--}1000\text{ K s}^{-1}$ cooling rates attainable routinely for real melts, constitutes a main limitation of atomistic MD simulations. Hence, the fictive temperature (T_f) of the glass model is markedly higher than that of the physical glass. The extremely rapid melt-cooling in MD simulations is also a source of skepticism by many researchers in the glass area. These problems are particularly acute for *ab initio* calculations, where for instance simulations involving the popular CPMD approach

nowadays involve similar cooling rates ($\geq 20 \text{ K ps}^{-1}$) as those employed by classical simulations 20–30 years ago. When also considering the significantly lower statistics of the structural parameters offered by the AIMD calculations (Section “Atom Ensembles”), their accuracy and precision might be overrated by the modeling research community.

Yet, the $\sim 10^{10}$ orders of magnitude more rapid cooling employed to prepare glass models by MD simulations relative to real glasses may not be as problematic as it appears: Firstly, the atom ensembles of laboratory-prepared glasses are $\approx 10^{17}$ – 10^{20} times larger than their modeled counterparts, which lowers the demand on the cooling rate for the latter to equilibrate (Corrales and Du, 2005). Secondly, force fields utilized in classical MD simulations are often developed (“fitted”) to reproduce experimentally derived structural parameters, which leads to a “self-compensation” effect because the force fields are constructed to mimic the structural features of the slowly quenched glass structure under conditions of much more rapid cooling.

Force Fields

The predictive power of classical MD simulations is crucially dependent on the precise choice of force fields to model the local interionic/interatomic interactions, which ultimately also control the medium-range organization of the ions/atoms. We start by discussing some general aspects of the force fields, which initially will assume that the atoms in the system are represented by electrostatic interactions among essentially hard spheres; such interatomic potentials are referred to as “rigid ion” force fields. More realistic interatomic potentials that mimic the presence of ion polarization effects (primarily the O species) are discussed in Section “Force Fields Accounting for Polarization Effects.”

Long-Range Coulombic Interactions

Evaluations of the interaction energy $U_{\alpha-\beta}^{jk}(r_{\alpha-\beta}^{jk})$ in a pair of atom/ion-species α and β with indices j and k that are separated at a distance $r_{\alpha-\beta}^{jk}$ need to account for both “long-range” Coulombic ($\approx 1 \text{ nm}$ and beyond) and more local “short-range” (yet, evaluated out to 0.5 – 1 nm) interactions involving both attractive and repulsive forces. In oxide-based glasses, the latter are normally dominated by O–O, M–O, and F–O pair-wise interactions. In contrast, the net Coulombic interaction energy is (formally) obtained by summing over all pairs of α and β species according to (Allen and Tildesley, 1987):

$$U(\text{Coulomb}) = \frac{1}{2} \sum_{\alpha, \beta} \sum_{j, k} \frac{q_{\alpha}^j q_{\beta}^k}{4\pi\epsilon_0 r_{\alpha-\beta}^{jk}}, \quad (2)$$

where the summation includes all interionic distances within a radius r_{max} , which is often referred to as the “cut-off” distance. To obtain a converged Coulomb energy, Eq. (2) is in practice calculated by a smoothed particle mesh Ewald summation (Essmann *et al.*, 1995).

The choice of charges q_{α}^j and q_{β}^k of the ions (“atoms”) is of pivotal importance for the performance of the force field. There are two options: The first assumes “formal” charges of each cation/anion species $\alpha = \{M^{z+}, F^{z+}, O^{2-}\}$, i.e., a charge equal to the (signed) oxidation number, yielding $q_{\alpha}^j = z_{\alpha}e$ in Eq. (2), where e is the elementary charge. However, it is well known that complete electron transfers are very rare in practice, notably so for the polymeric networks of oxide-based glasses. Consequently, *partial charges* are more commonly assumed, which may be expressed $q_{\alpha}^j = k_{\alpha} z_{\alpha} e$, where $k_{\alpha} < 1$. Examples of popular force fields constructed around partial charges are those of “BKS” (van Beest *et al.*, 1990) and “Teter” (Cormack *et al.*, 2002). Note that the charges q_{α}^j may also enter the functionals describing the more localized interaction terms discussed below, although such cases are relatively rare.

Short-Range Interactions

We next consider the short(er)-range interaction component of the force-field, which is required to avoid a “system collapse” due to the typically predominant attractive Coulombic forces. Hence, these interatomic potentials always include a repulsive term that dominates at short distances $r_{\alpha-\beta}^{jk}$, the most common parameterization being that of Born and Mayer (1932):

$$U(\text{Born–Mayer}) \equiv U_{\alpha-\beta}^{jk}(r_{\alpha-\beta}^{jk}) = A_{\alpha-\beta} \exp\left\{-r_{\alpha-\beta}^{jk}/\rho_{\alpha-\beta}\right\}, \quad (3)$$

where $A_{\alpha-\beta}$ and $\rho_{\alpha-\beta}$ are parameters. Note that the summation over all pairs in the structure [as indicated in Eq. (2)] is omitted in Eq. (3) and those that follow below. The by far most popular force-field functional utilized in MD simulations of oxide-based glasses is that of Buckingham (1938):

$$U(\text{Buckingham}) \equiv U_{\alpha-\beta}^{jk}(r_{\alpha-\beta}^{jk}) = A_{\alpha-\beta} \exp\left\{-r_{\alpha-\beta}^{jk}/\rho_{\alpha-\beta}\right\} - C_{\alpha-\beta} \cdot \left(r_{\alpha-\beta}^{jk}\right)^{-6}, \quad (4)$$

which besides the Born–Mayer form [Eq. (3)] also includes an r^{-6} -dependent attractive interatomic potential term [hence its negative sign in Eq. (4)], analogously to that of the well-known Lennard–Jones potential that accounts for interactions between two (induced) dipoles (Allen and Tildesley, 1987). However, as inclusion of the attractive term in Eq. (4) may lead to insufficient repulsive forces among the particles at very short interatomic distances, and thereby a system collapse during the course of the calculations, it is customary to additionally include another (empirically deduced) repulsive term of the form $D_{\alpha-\beta} \cdot \{r_{\alpha-\beta}^{jk}\}^{-n}$ with

$6 < n \leq 12$ in the Buckingham potential (where n may be a non-integer number). Although the Born–Meyer/Buckingham functionals are most frequently adopted in atomistic modeling of oxide-based glasses by MD simulations, other functional forms of the interatomic energy are encountered, such as that of Morse (Morse, 1929):

$$U(\text{Morse}) \equiv U_{\alpha-\beta}^{jk} \left(r_{\alpha-\beta}^{jk} \right) = D_{\alpha-\beta} \left(\left[1 - \exp \left\{ -a_{\alpha-\beta} \left(r_{\alpha-\beta}^{jk} - r_{\alpha-\beta}^0 \right) \right\} \right]^2 - 1 \right), \quad (5)$$

where $\{D_{\alpha-\beta}, a_{\alpha-\beta}, r_{\alpha-\beta}^0\}$ are parameters. In analogy with the relationship between the Born–Meyer (Eq. (3)) and Buckingham [Eq. (4)] pair potentials, the repulsive Morse functional may also be combined with additional attractive or repulsive terms (Pedone et al., 2006).

Force Fields Accounting for Polarization Effects

Although a multitude of options exist for mimicking polarization effects of the ions/atoms, those employed in atomistic MD simulations of oxide glasses may largely be grouped into two classes: *shell models* (Dick and Overhauser, 1958; Sanders et al., 1984) and *polarized ion models* (PIM) (Wilson et al., 1996; Madden and Wilson, 1996).

The most common shell-model force fields employed in simulations of silicate-based glasses build on that introduced by Sanders and co-workers for amorphous SiO_2 (Sanders et al., 1984). Here, all M^{z+}/F^{z+} cations bear full formal charges, but each O^{2-} ion is represented by a core (O_C^i) and a shell (O_S^j) portion with masses m_C^i and m_S^j , respectively, and corresponding charges $z_C = +0.8482e$ and $z_S = -2.8482e$ that obeys $z_C^i + z_S^j = -2$. Here, the “electron-cloud”-emulating “shell” has a minute mass, thereby requiring a very short time-step (0.2 fs) for integrating the equations of motion. This renders shell-model simulations much more time-consuming than their rigid-ion counterparts, yet comparable (or even faster) than those involving PIM force fields. The core-shell units are connected by a harmonic potential of the form

$$U(\text{core-shell}) \equiv U_{C-S}^{ij} \{ r_{C-S}(\text{O}_C^i - \text{O}_S^j) \} = \frac{1}{2} k_{C-S} [r_{C-S}(\text{O}_C^i - \text{O}_S^j)]^2, \quad (6)$$

where k_{C-S} is the force constant. Eq. (6) is in practice added to the Buckingham potential [Eq. (4)] or another interatomic functional, where all cation-shell interactions are considered in the summation, i.e., all $F^i-\text{O}_S^k$ and $M^j-\text{O}_S^k$ pairs, as well as $\text{O}_S^i-\text{O}_S^k$ from distinct O atom pairs.

The PIM force field and variations thereof, such as the aspherical ion model (AIM) (Jahn and Madden, 2007), also assume formal charges of all ions, but implement polarization effects of each atom/ion by solving a set of equations so as to minimize its polarization energy at each time step of the simulation (Wilson et al., 1996; Jahn and Madden, 2007). PIM/AIM force fields have proven useful for improving the accuracy of the modeling of (for instance) vitreous B_2O_3 and borosilicate glasses (Maranas et al., 2001; Zeidler et al., 2014; Pacaud et al., 2017).

Three-Body Interatomic Potentials

All interatomic potentials considered thus far only described *atom-pair* interactions. A force field that faithfully accounts for the glass structure without relying on explicit control of atoms within larger aggregates—i.e., multi-body interactions—presents decisive advantages in that any “longer-range” order is not artificially introduced. Consequently, and in sharp contrast to the common simulation strategies of molecular systems—such as organic molecules where three- and four-body interactions are normally always accounted for (Vanommeslaeghe et al., 2014)—atomistic MD simulations of glasses should ideally avoid explicit consideration of many-body interactions. Indeed, their necessity reflects imperfect performance of the pair-potentials. However, for network-forming species such as SiO_4 and PO_4 , it is not uncommon that the force fields (regardless of whether they are of rigid-ion or shell-model types) also implement three-body terms to control the O–Si–O and O–P–O *intratetrahedral* angles to remain close to the ideal value 109.47° . Such precautions avoid unrealistic deviations from the tetrahedral geometry, but should be avoided for groups such as AlO_4 and BO_4 , because tight constraints around a tetrahedral geometry precludes transitions between coordination numbers, such as $\text{B}^{[4]} \rightarrow \text{B}^{[3]}$ and $\text{Al}^{[4]} \rightarrow \text{Al}^{[5]}$, which are commonly encountered in borate/borosilicate (Section “*Borates and Borosilicates*”) and aluminosilicate (see Section “*Aluminosilicates*”) glasses, respectively, that incorporate high-field modifiers. Here, determining the corresponding relative BO_3/BO_4 and $\text{AlO}_4/\text{AlO}_5/\text{AlO}_6$ populations is key to characterizing the glass structure and properties.

Evaluation of Short-Range Structural Parameters

Short-range structural parameters, such as bond lengths and intrapolyhedral angles, are readily extracted from an MD-derived glass model. The (average) interatomic distance of an atom pair E – F may be evaluated by using the *radial distribution function* (RDF). It essentially projects the 3D structure onto a one-dimensional distance-dependent function that provides the probability of finding an atom of species F at a distance (radius) r from E . As it involves atom-pairs, the RDF is often referred to as the *pair distribution function* (PDF). Fig. 4 shows the PDF for the Si–O pair in a borophosphosilicate glass. It shows a strong peak at 164 pm, which corresponds to the *most probable* Si–O distance in the glass model. The *average* Si–O distance is obtained by integrating the product $r_{\text{Si-O}} \cdot \text{PDF}(r_{\text{Si-O}})$ over all distances $r_{\text{Si-O}}$. For increasing $r_{\text{Si-O}}$, the values of the PDF first diminish, but then approach the asymptotic value of unity;

Fig. 4 MD-derived pair-distribution function (PDF) for the Si-O pair in a silicate-based glass of stoichiometry $24\text{Na}_2\text{O}-23\text{CaO}-15\text{B}_2\text{O}_3-34\text{SiO}_2-4\text{P}_2\text{O}_5$ (Yu *et al.*, 2017). The first maximum reveals the closest Si-O distance, while integrating the PDF out to its first minimum (marked by the triangle) provides the average coordination number $\bar{Z}_{\text{Si}}$, i.e., the number of O atoms in the first coordination sphere of Si. Note that the asymptotic PDF value of 1.0 is observed for large $r_{\text{Si-O}}$ distances.

this common property of all pair distribution functions reflects that the probability of finding another O at long distances $r_{\text{Si-O}}$ is unity. Moreover, integrating $\text{PDF}(r_{E-F})$ out to its first minimum yields the average coordination number of E with respect to F. In the case of Si-O, this implies $\bar{Z}_{\text{Si}} = 4$, as expected for SiO_4 tetrahedra. A triangle marks the distance ($r_{\text{Si-O}} \approx 200$ pm) at the PDF minimum in Fig. 4, i.e., the “cut-off” distance used in the integration.

We next consider the PDFs displayed for the various cation-oxygen atom pairs in the left panel of Fig. 5, all of which were observed from a borophosphosilicate glass of composition $24\text{Na}_2\text{O}-23\text{CaO}-15\text{B}_2\text{O}_3-34\text{SiO}_2-4\text{P}_2\text{O}_5$ (see Fig. 1), except for the $\text{PDF}(r_{\text{Al-O}})$ results that were obtained from a La aluminosilicate glass. Besides the net PDF of Si-O, $\text{PDF}(r_{\text{Si-O}})$, Fig. 5(a) also includes the $\text{PDF}(r_{\text{Si-BO}})$ and $\text{PDF}(r_{\text{Si-NBO}})$ components: The latter reveals a slightly shorter (most probable) distance of $r_{\text{Si-NBO}} = 161$ pm than that of the Si-BO pair ($r_{\text{Si-BO}} = 165$ pm). This is expected, because the Si-NBO bond length is shorter than its Si-BO counterpart, while the net Si-O bond length $r_{\text{Si-O}} = 164$ pm is the weighted average of the two $r_{\text{Si-NBO}}$ and $r_{\text{Si-BO}}$ distances, where the PDFs of Fig. 5(a) reveal a domination of Si-BO pairs. The PDFs for P-O, Al-O, and Na-O are shown in Fig. 5(c), (e), and (g), respectively. Note the bond-distance order $r_{\text{P-O}} < r_{\text{Si-O}} < r_{\text{Al-O}} < r_{\text{Na-O}}$, as well as the concurrent broadening of the PDFs. These trends mirror that of a decreasing cation field strength (CFS), where the CFS of M^{z+} is given by z/r^2 , and r is the ion radius. Consequently, a small ion of high charge controls the O atoms in its first coordination shell more tightly than a larger ion of lower charge.

The right panel of Fig. 5 plots the bond-angle distributions (BADs) of selected polyhedra in the borophosphosilicate glass. As expected, the intratetrahedral O-Si-O angles of the SiO_4 tetrahedra are 109.5° [Fig. 5(b)], while the average O-B^[3]-O angle of the planar BO_3 groups is close to 120° [Fig. 5(d)]. Moreover, Figs. 5(f) and (h) show the Si-O-Si and Al-O-Al intertetrahedral BADs (the latter obtained from a La aluminosilicate glass model). Note the small peak at 94° observed for the Al-O-Al BAD, which stems from a minor degree of edge-shared polyhedra that primarily involve AlO_5 and AlO_6 moieties (Okhotnikov *et al.*, 2013).

Modeling of Various Glass Systems

Silicates

The network organization of silicate glasses involving one or several glass-network modifiers has been studied extensively both experimentally and by modeling. The central tasks involve determining (1) the set of coexisting Q_{Si}^n species and their corresponding fractional populations $\{x_{\text{Si}}^n\}$, as well as (2) how the various Q_{Si}^n tetrahedra are (preferentially) interlinked. The $\{Q_{\text{Si}}^n\}$ speciation (“silicate speciation”) may readily be determined for binary $M_2\text{O-SiO}_2$ glasses by Raman or ^{29}Si MAS NMR spectroscopy (Greaves and Sen, 2007; Edén, 2012). We comment that although the $\{Q_{\text{Si}}^n\}$ speciation is often (incorrectly) referred to as a medium-range structural feature, it merely represents statistics on the short-range structure, as it conveys the relative numbers of Si-BO and Si-NBO bonds at the SiO_4 tetrahedra, which are the smallest building units of the glass network (see Section “Glass Building Blocks”). Likewise, while the intratetrahedral O-Si-O bond angles of the SiO_4 groups reflect the short-range structure (Section “Evaluation of Short-Range Structural Parameters”), the intertetrahedral Si-O-Si counterpart [see Fig. 5(f)] is a medium-range structural parameter, as are the $Q_{\text{Si}}^n-Q_{\text{Si}}^m$ interconnectivities [problem (2)]. As such, the latter is much more difficult to probe experimentally than the $\{Q_{\text{Si}}^n\}$ speciation. Here, double-quantum (2Q) ^{29}Si MAS NMR is a most promising option, although it has hitherto only been applied to a few binary $M_2\text{O-SiO}_2$ glasses with $M = \{\text{Na}, \text{K}\}$ (Olivier *et al.*, 2001; Malfait *et al.*, 2007). However, atomistic MD simulations may readily address both problems (1) and (2), each of which is discussed below.

The distribution of BO and NBO species among the SiO_4 tetrahedra in the silicate glass, i.e., the set of $\{x_{\text{Si}}^n\}$ populations, is generally intermediate of two limiting scenarios: (i) A binary BO/NBO distribution (Edén *et al.*, 2011), which implies the coexistence of (at most) two distinct tetrahedral units, Q_{Si}^n and Q_{Si}^{n+1} (whose fractional populations obey $x_{\text{Si}}^n + x_{\text{Si}}^{n+1} = 1$), except for

Fig. 5 Left panel: PDFs for the pairs (a) Si-O, (c) P-O, (e) Al-O, and (g) Na-O. Besides the net Si-O PDF, the plot in (a) also provides the results for its Si-BO and Si-NBO components. Right panel: Bond-angle distribution (BAD) functions for (b) O-Si-O, (d) O-B^[3]-O, (f) Si-O-Si, and (h) Al-O-Al. Note that the angles in (b) and (d) concern the *intratetrahedral* and *intratriangular* bond angles of SiO₄ and BO₃ moieties, respectively, whereas (f, h) inform about *intertetrahedral* angles. The respective average E-O bond-lengths (in pm), as well as O-E-O and E-O-E bond angles (in degrees) are specified in each diagram. All results were generated by classical MD simulations of a borophosphosilicate glass of stoichiometry 24Na₂O-23CaO-15B₂O₃-34SiO₂-4P₂O₅, except for those in (e, h) that were obtained from an aluminosilicate glass of composition 17La₂O₃-28Al₂O₃-55SiO₂. Parts (a-d, f, g) are reproduced from [Stevensson, B., Yu, Y., Edén, M., 2018. Structure-composition trends in multicomponent borosilicate-based glasses deduced from molecular dynamics simulations with improved B-O and P-O force fields. *Phys. Chem. Chem. Phys.* 20, 8192-8209], with permission from PCCP Owner Societies. Parts (e, h) are reproduced from [Okhotnikov, K., Stevensson, B., Edén, M., 2013. New interatomic potential parameters for molecular dynamics simulations of rare-earth (RE = La, Y, Lu, Sc) aluminosilicate glass structures: Exploration of RE³⁺ field-strength effects. *Phys. Chem. glass stoichiometries associated with $\bar{N}_{\text{BO}}^{\text{Si}} = 0, 1, 2, 3$ and 4, for which the network is assumed to comprise one sole Q_{Si}^n type with $n = \bar{N}_{\text{BO}}^{\text{Si}}$; (ii) A *random* distribution, where the NBO ions are shared statistically among the tetrahedra, such that each Q_{Si}^n population (x_{Si}^n) is obtained from a binomial distribution (Lacy, 1965; Edén *et al.*, 2011). While experiments reveal that most Na₂O-SiO₂ glasses conform well to the binary model (Edén, 2012), the BO/NBO distribution in $\text{MO}_{z/2}$ -SiO₂ glasses deviate progressively from a binary n -distribution for increasing modifier content, as well as for an increase in either the field strength of the M^{z+} cation or the melt-cooling rate (and thereby T_f). Such elements of “randomness” may be accounted for by “disproportionation equilibria”, such as $2Q_{\text{Si}}^n \rightleftharpoons Q_{\text{Si}}^{n-1} + Q_{\text{Si}}^{n+1}$ with $n = 1, 2, 3$ (Stebbins, 1988; Maekawa *et al.*, 1991). Consequently,

silicate glasses incorporating alkaline earth (M^{2+}) cations manifest a significant “randomization” in their $\{Q_{Si}^n\}$ distributions due to the moderately high CFS of the network modifiers.

Atomistic MD simulations of silicate-based glasses reveal in general at least three co-existing Q_{Si}^n species (Pedone *et al.*, 2010; Mathew *et al.*, 2014), where deviations from the binary $\{Q_{Si}^n, Q_{Si}^{n+1}\}$ scenario are evident even for binary Na_2O-SiO_2 glasses (Du and Cormack, 2004). Hence, MD simulations tend to overestimate the “randomness” of the $\{Q_{Si}^n\}$ speciation relative to experiments. This partially stems from the higher fictive temperatures associated with the glass models, stemming from the high cooling rates employed in the glass model production (see Section “The Cooling Rate”). However, the accuracy of the modeled $\{Q_{Si}^n\}$ speciation relative to its experimental counterpart also depends on the choice of force field, where shell-model calculations generally provide $\{x_{Si}^n\}$ sets closer to experiments (e.g., see Tilocca, 2008; Fortino *et al.*, 2019).

The degree of discrepancies between $\{Q_{Si}^n\}$ speciations obtained by ^{29}Si MAS NMR and atomistic shell-model MD simulations may be gauged from Fig. 6, which displays results from $Na_2O-CaO-SiO_2-P_2O_5$ glasses with increasingly polymerized networks, i.e., increasing $\bar{N}_{BO}^{Si}$. (Notably, the glass design implied that the low P_2O_5 contents had little bearings on the $\{Q_{Si}^n\}$ distribution; see Mathew *et al.*, 2014). Also shown are the predictions from the “binary” and “random” BO/NBO bonding scenarios. The presence of large amounts of Ca^{2+} cations of relatively high field strength ($1.5 \lesssim n_{Na}/n_{Ca} \lesssim 1.8$) implies significant deviations from a simple binary $\{Q_{Si}^n\}$ speciation, where the ^{29}Si NMR-derived results reveal predominantly three coexisting $\{Q_{Si}^{n-1}, Q_{Si}^n, Q_{Si}^{n+1}\}$ groups in each glass, whereas the glass models are intermediate between the two limiting binary/random n -distributions, meaning that they manifest noticeably wider $\{Q_{Si}^n\}$ ensembles than that of a binary distribution (as well as their NMR-derived counterparts), yet the co-existence of fewer Q_{Si}^n species than the prediction from a statistical BO/NBO partitioning among the SiO_4 groups.

We next consider the intermixing of the various Q_{Si}^n groups in binary silicate glasses. According to Zachariasen’s *random network model* (RNM) (Zachariasen, 1932), both the Q_{Si}^n species and the network-modifier ions are randomly distributed across the structure. Such a glass lacks medium-range order because there is no preference for any particular $Q_{Si}^n-Q_{Si}^m$ connectivity. Over the past few decades, however, many experiments and MD simulations suggest that silicate glasses merely comprise SiO_4 -rich domains involving predominantly $Q_{Si}^4-Q_{Si}^4$ motifs that are interleaved with modifier-rich “channels” at their boundaries; the latter are built predominantly by lower- n Q_{Si}^n groups ($n \leq 3$); see Greaves (1985), Olivier *et al.* (2001), and Du and Cormack (2004) and references therein. Such a structural scenario, termed the *modified random network model* (MRNM), was introduced by Greaves and colleagues (Greaves *et al.*, 1981; Greaves, 1985), building on earlier ideas by Bockris *et al.* (1955). Notably, it is not restricted to binary silicate glasses, but is also advocated from experiments and MD simulations of aluminosilicate glasses (Le Losq *et al.*, 2017; Ganisetti *et al.*, 2019).

The MRNM implies structural domains rich in NBO ions and network modifiers, that co-exist with Q_{Si}^4 -dominated portions. Hence, probing the spatial distribution of the network modifiers provides an independent assessment of the structural inhomogeneities inherent to the MRNM. Although early ^{23}Na NMR experiments on Na_2O-SiO_2 glasses did not reveal any pronounced Na clustering (Gee and Eckert, 1995), subsequent MD simulations suggested slight Na aggregation tendencies (Du and Cormack, 2004). Moreover, both NMR experiments and MD simulations on silicate glasses incorporating cations with relatively high CFS (e.g., Li^+) accord in their inferences of a non-negligible network-modifier clustering (Voigt *et al.*, 2005).

Phosphates and Phosphosilicates

As their silicate analogs, $M_{(2)}O-P_2O_5$ glasses form polymeric networks of interconnected phosphate tetrahedra with variable number of BO/NBO species at the Q_P^n moieties. However, modeling of the structures of phosphate glasses (without any network co-formers) by MD simulations has received comparatively little attention. Nonetheless, studies of the $\{Q_P^n\}$ speciations in binary $Li_2O-P_2O_5$ (Liang *et al.*, 2000), $ZnO-P_2O_5$ (Tischendorf *et al.*, 2003), and $FeO-P_2O_5$ (Al-Hasni and Mountjoy, 2011) glasses are reported, as well as the distribution of coordination numbers of the respective Li^+ , Zn^{2+} , and Fe^{2+}/Fe^{3+} cations. Out of the relatively sparse modeling studies of phosphate glasses, most were published during the last decade and targeted modifier-rich $Na_2O-CaO-P_2O_5$ glasses (reviewed below), stemming from their potential use as *bioactive glasses* for biomedical implants (Christie *et al.*, 2017).

The structural role of P has been explored extensively in various glass systems that involve multiple glass network formers by atomistic modeling, notably so bioactive glasses from the $Na_2O-CaO-SiO_2-P_2O_5$ system. Such glasses degrade in body fluids and have the capacity to integrate with bone/tooth tissues. Consequently, they are exploited for bone grafting and tissue engineering applications (Hench, 1991). The first bioactive glass composition—and hitherto also the clinically most utilized—has the stoichiometry $24.6Na_2O-26.7CaO-46.1SiO_2-2.6P_2O_5$ and is termed “45S5 Bioglass®” (Hench, 1991). Both *in vivo* and *in vitro* bioactivity assessments suggest that the bioactivity (“bone-bonding capacity”) enhances concurrently with the P_2O_5 content of the glass (up to ≈ 6 mol%, beyond which glass-in-glass separation occurs), which is hypothesized to largely stem from the structural role of P, whose speciation is dominated by readily released orthophosphate (Q_P^0) groups for the most bioactive glass compositions. Bioactive $Na_2O-CaO-SiO_2-P_2O_5$ glasses feature silicate networks of low polymerization degree ($2.1 \leq \bar{N}_{BO}^{Si} \leq 2.6$) so as to be readily degradable in body fluids (Edén, 2011). For increasing silicate network connectivity, i.e., lower NBO content of the glass (but independently on the amount of P), the fractional population of Q_P^0 groups (x_P^0) is decreased, whereupon Q_P^1 species forms, as evidenced both by MD simulations and NMR experiments (Mathew *et al.*, 2014).

Modeling by atomistic MD simulations have sought to improve the insight into the composition–structure–dissolution trends. The initial modeling work on bioactive glasses have contributed significantly to the present understanding of the structure of bioactive glasses, such as predicting that the more polymerized Q_P^1 species are linked to a silicate tetrahedron *via* a Si–O–P linkage (Tilocca and de Leeuw, 2006; Tilocca and Cormack, 2007; Tilocca *et al.*, 2007), as opposed to P–O–P, as was (is still) often

Fig. 6 Q^n_{Si} fractional populations $\{x^n_{Si}\}$ from different Na_2O – CaO – SiO_2 – P_2O_5 phosphosilicate glasses determined either by ^{29}Si NMR or shell-model MD simulations, and plotted against the number of BO atoms (n) at each SiO_4 group. Results are shown for increasing average silicate network connectivity N_{BO}^{Si} ; note that the glasses also comprise ≤ 6 mol% P_2O_5 , but nearly all P is present as orthophosphate groups that do not contribute to the network. The experimental and modeled data are compared with the predictions from binary and random NBO/BO distribution calculated from the expressions of Edén *et al.* (2011). Toward a rational design of bioactive glasses with optimal structural features: Composition-structure correlations unveiled by solid-state NMR and MD simulations. *J. Phys. Chem. B* 118, 833–844].

speculated in the literature. Yet, the low P contents (a few at%) in bioactive glasses present some hurdles: The $\{Q^n_P\}$ speciations from AIMD simulations are highly imprecise due to the insufficient statistics available from the few P atoms in the atom ensembles (see Section “Salient Features of Atomistic MD Simulations”), while current force fields in classical MD simulations cannot accurately reproduce the markedly stronger propensity for P–NBO contacts relative to Si–NBO at practically accessible melt-quench rates $q_C \leq 1 \text{ K ps}^{-1}$. Consequently, the Q^1_P (and Q^2_P) populations become overestimated at the expense of the

orthophosphate counterpart. Yet, the latter is shown experimentally to dominate the phosphate speciations in all Na_2O – CaO – SiO_2 – P_2O_5 glass compositions that exhibit sufficiently large $\text{Na}^+/\text{Ca}^{2+}$ contents for balancing all negative charges of the Q_p^0 tetrahedra (Pedone *et al.*, 2010; Mathew *et al.*, 2014). The limitations of *quantitative* predictions of $\{\text{Q}_\text{p}^n\}$ speciations by classical MD simulations are most acute for relatively polymerized glass networks ($\overline{N}_{\text{BO}}^{\text{Si}} \gtrsim 2.3$) (Stevensson *et al.*, 2018).

Most CPMD or classical MD simulation efforts to model the phosphate speciations in bioactive glasses targeted the 45S5 glass composition (Tilocca and de Leeuw, 2006; Tilocca *et al.*, 2007; Tilocca and Cormack, 2007; Pedone *et al.*, 2010; Xiang and Du, 2011; Tilocca, 2013; Mathew *et al.*, 2014). For a standard cooling rate of 10 K ps^{-1} , MD simulations employing shell-model P–O force fields typically yield orthophosphate fractions in a range from 0.73 (Pedone *et al.*, 2010) to 0.93 (Stevensson *et al.*, 2018), whereas analogous calculations based on rigid-ion force fields produce significantly lower values of $x_\text{p}^0 \approx 0.5$ (Tilocca, 2008; Xiang and Du, 2011). These numbers may be contrasted with the experimental result $x_\text{p}^0 = 0.96$ obtained by ^{31}P MAS NMR (Mathew *et al.*, 2014). Notwithstanding that the extremely rapid quench rates of the simulations partially account for the underestimated orthophosphate fractions—and thereby overestimated degree of Si–O–P bonding (Tilocca, 2013)—the *primary* deficiency originates from current force field parameterizations used in classical MD simulations, as discussed—and also partially remedied—by Stevensson *et al.* (2018). There should be significant room for future force-field improvements.

The medium-range structural organization of bioactive glasses potentially also influences their degradation properties in aqueous media. Hence, atomistic MD simulations have been employed to assess features such as the network organization in terms of chain lengths and ring sizes of silicate groups (Tilocca, 2013), also encompassing modeling of the glass surface at which the reactions occur that ultimately leads to glass degradation (Tilocca and Cormack, 2010; Berardo *et al.*, 2013). Moreover, the spatial distribution of the orthophosphate anions across the glass structure is likely to affect their leaching into the surrounding body fluids. While early MD simulations indicated a non-negligible clustering of the orthophosphate anions even in fragmented glasses such as 45S5 (Tilocca and Cormack, 2007; Tilocca *et al.*, 2007), more recent simulations suggest a near—random distribution of the Q_p^0 moieties around the silicate network, in full consistency with direct experimental constraints from $2\text{Q } ^{31}\text{P}$ NMR experiments (Stevensson *et al.*, 2014).

Although still very sparse, combined use of MD simulations and non-routine solid-state NMR experimentation on bioactive phosphosilicate glasses—as well as B-bearing analogs (see Fig. 1)—is a most promising route to advance the insight into their composition-structure-bioactivity relationships (Pedone *et al.*, 2010; Stevensson *et al.*, 2014; Mathew *et al.*, 2015; Yu *et al.*, 2017, 2019).

MD simulations of (Si-free) bioactive phosphate glasses have thus far almost exclusively focussed on $(55-x)\text{Na}_2\text{O}$ – $x\text{CaO}$ – $45\text{P}_2\text{O}_5$ compositions with variable Na and Ca contents (i.e., x specifies mol%), for which both AIMD and shell-model MD simulations are reported (Tang *et al.*, 2010; Di Tommaso *et al.*, 2013; Ainsworth *et al.*, 2012; Christie *et al.*, 2013). These glasses are associated with an average phosphate network connectivity of $\overline{N}_{\text{BO}}^{\text{P}} = 1.8$, meaning that the networks are built primarily from Q_p^2 (major) and Q_p^1 (minor) groups. Yet, notwithstanding that $\overline{N}_{\text{BO}}^{\text{P}}$ is fixed, experiments demonstrate that the glass solubility in water diminishes concurrently for increasing Ca content. This feature was shown to stem from the enhanced cross-linking of *distinct* network fragments by the higher CFS Ca^{2+} species: The higher Ca–NBO affinity implies a higher coordination of NBO species from phosphate groups located at different network segments as compared with Na^+ , which merely coordinates BO atoms from neighboring PO_4 tetrahedra of the *same* network fragment (Christie *et al.*, 2013, 2017).

Aluminosilicates

Besides modified (phospho)silicate glasses, amorphous aluminosilicates have probably attracted most attention in the MD simulation community. The focus on the modeling activities also matches well that of the experimental counterparts, where the Na_2O – Al_2O_3 – SiO_2 and (particularly) the CaO – Al_2O_3 – SiO_2 glass systems are particularly well studied (Himmel *et al.*, 1991; Cormier *et al.*, 2003; Pedone *et al.*, 2012; Jakse *et al.*, 2012; Xiang *et al.*, 2013; Bouhadja *et al.*, 2014; Atila *et al.*, 2019). Here, the structural role of Al and its intermixing with Si in the aluminosilicate glass networks represent key structural features that have been addressed experimentally, as well as by AIMD and classical MD simulations.

We start by briefly outlining the current understanding of aluminosilicate glass structures, such as that conveyed by the structural fragment in Fig. 7(a). From information gathered over the past 20 years, this structural picture is known not to hold strictly, but it nevertheless captures the most fundamental aspects. Moreover, it is also largely supported by atomistic MD simulations. Yet, the latter have assisted the experiments in clarifying some important deviations from the relatively simple set of rules governing the structure of aluminosilicate glasses [Fig. 7(a)]: Provided that a M^{z+} -bearing aluminosilicate glass with stoichiometry $n_{\text{M}}\text{MO}_{z/2}$ – $n_{\text{Al}}\text{AlO}_{3/2}$ – $n_{\text{Si}}\text{SiO}_2$ obeys the following criteria, (A) $n_{\text{Al}}/n_{\text{M}} \leq z$ and (B) $n_{\text{Al}}/n_{\text{Si}} \leq 1$, the glass network consists predominantly of corner-shared Q_{Si}^n and Q_{Al}^4 tetrahedra interconnected *via* Si–O–Si and Si–O–Al^[4] bonds, while all NBO species are located solely at the SiO_4 groups and Al^[4]–O–Al^[4] linkages are absent. All these features are direct consequences of the excess negative charge of each Q_{Al}^4 group (i.e., $[\text{AlO}_4]^-$), which lead to the “Loewenstein Al avoidance” (see Section “Structural Order”), as well as to the reluctance of Q_{Al}^4 groups to accommodate additional negative charges, meaning that Al^[4]–NBO bonds are absent (Engelhardt and Michel, 1987; Edén, 2015). If any of the criteria (A) and (B) is violated, the glass network responds by minimizing the number of Al^[4]–O–Al^[4] linkages by the formation of higher coordination Al^[5] (AlO_5) and Al^[6] (AlO_6) species. This occurs either whenever $n_{\text{Al}}/n_{\text{Si}} > 1$, or when incomplete charge-compensation is available from the glass-network modifiers ($n_{\text{Al}}/n_{\text{M}} > z$).

Yet, even aluminosilicate glasses that indeed obey both criteria (A) and (B) deviate from the (oversimplified) structural picture outlined above. The extent of such deviations depends on the CFS of the M^{z+} cations (Edén, 2015). For increasing M^{z+} field

Fig. 7 (a) MD-generated structural fragment representative of a Si-rich and highly polymerized Na₂O–Al₂O₃–SiO₂ glass, forming a network of corner-shared Q_{Si}^n and Q_{Al}^4 tetrahedra. This model conforms well to the conventional structural picture of aluminosilicate glasses (Section “Aluminosilicates”). (b) A structural fragment from a Y₂O₃–Al₂O₃–SiO₂ glass model (Iftekhar *et al.*, 2012). The high CFS of Y³⁺ induces the following “unconventional” structural features, not observed in the Na-based counterpart in (a): (1) Significant amounts of AlO₅ and AlO₆ polyhedra that frequently connect to other polyhedra by edge-sharing; (2) direct Al^[4]–O–Al^[4] linkages that violates the Loewenstein’s Al avoidance; (3) AlO₄ groups with NBO ions (Al^[4]–NBO bonds). Moreover, besides the BO/NBO species, (4) oxygen triclusters (O^[3]) and (5) free O^{2–} ions (O^[0]) are present.

strength, the glass structure tends to “randomize”, which is reflected in (i) a high disorder of the intermixing of the SiO₄/AlO₄ network groups; (ii) progressively increasing AlO₅ and AlO₆ populations; and (iii) a stabilization of Al^[4]–NBO bonds, which alters the NBO-partitioning among the SiO₄ and AlO₄ tetrahedra (Edén, 2015). For instance, tectosilicate glasses feature $n_{\text{Al}} = n_{\text{Si}} = zn_M$ and are thereby expected to manifest fully polymerized 3D aluminosilicate networks with strictly alternating Q_{Si}^4 and Q_{Al}^4 groups. Yet, ²⁷Al and ¹⁷O MAS NMR experiments reveal a few percent of NBO species in such CaO–Al₂O₃–SiO₂ glasses, as well as minor AlO₅ populations ($\lesssim 7\%$ out of the entire $\{\text{Al}^{[p]}\}$ speciation), whereas their Na₂O–Al₂O₃–SiO₂ analogs of similar compositions adhere much closer to the conventional aluminosilicate glass picture outlined above (Stebbins and Xu, 1997; Edén, 2015).

Ca- and Na-based aluminosilicate glass models generated either by classical shell model MD simulations (followed by energy minimization by DFT) (Pedone *et al.*, 2012), or by rigid-ion force fields (Xiang *et al.*, 2013), overall reproduce the experimental findings outlined above. The glass models also confirm that the violation of the Loewenstein Al avoidance is larger for glasses that incorporate solely the higher-CFS Ca²⁺ cation than those involving solely Na⁺ or a mixture of Na⁺ and Ca²⁺. Nonetheless, even the largest fraction of Al^[4]–O–Al^[4] linkages observed out of the BO speciation remained modest ($\leq 6\%$) (Pedone *et al.*, 2012). Similar results were observed from MD simulations of SrO–Al₂O₃–SiO₂ glasses (Charpentier *et al.*, 2018). In contrast and contrary to expectations, markedly higher abundances of Al^[4]–O–Al^[4] bridges are reported from recent MD simulations using rigid-ion force fields for CaO–Al₂O₃–SiO₂ glasses (Atila *et al.*, 2019), a mixed Ca/Mg aluminosilicate glass (Ganisetti *et al.*, 2019), and even in glasses simultaneously incorporating the low-CFS Na⁺ and K⁺ cations (Le Losq *et al.*, 2017). However, all those studies only had, at best, qualitative experimental support for the significant violations of the Loewenstein rule revealed by the glass models.

Moreover, previous suggestions/predictions (Mysen *et al.*, 1980; Lee and Sung, 2008) about distinct structural roles of Na⁺ and Ca²⁺ species in mixed-cation Na₂O–CaO–Al₂O₃–SiO₂ glasses were confirmed by MD simulations: While the monovalent Na⁺ cations mainly serve as charge-compensators of the $[\text{AlO}_4]^-$ tetrahedra, the Ca²⁺ counterparts preferentially act as modifiers (thereby charge-balancing Si–NBO motifs of the Q_{Si}^n groups) (Gambuzzi *et al.*, 2014).

Notwithstanding that both experiments and MD simulations reveal negligible deviations from the conventional aluminosilicate structural picture for Na-based glasses [see Fig. 7(a)], and very modest discrepancies for those involving Ca²⁺ cations with moderately high field-strength, significantly altered glass networks are observed for glasses incorporating Mg²⁺ or trivalent rare-earth (RE³⁺) cations: this is illustrated by Fig. 7(b) that displays an MD-generated glass model of an Y-based glass of composition Y_{0.56}Al_{0.40}SiO_{3.44}

(which notably obeys both criteria of (A) and (B) above). For $\text{RE}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ glasses along the series of increasing RE^{3+} CFS— $\text{La}^{3+} < \text{Y}^{3+} < \text{Lu}^{3+} < \text{Sc}^{3+}$ —both NMR experiments and classical MD simulations reveal the following trends (Iftekhar *et al.*, 2012; Jaworski *et al.*, 2012; Okhotnikov *et al.*, 2013; Jaworski *et al.*, 2015, 2016): (1) The fractional populations of $\text{AlO}_5/\text{AlO}_6$ polyhedra is dramatically increased, where AlO_5 polyhedra account for $\approx 8\%$ and $\approx 30\%$ in La and Sc based glasses, respectively; (2) the $\text{SiO}_4/\text{AlO}_4$ intermixing manifests a significant disorder in all RE-based glasses, where $\text{Al}^{[4]}\text{--O--Al}^{[4]}$ are abundant network motifs, while (3) the relative preference for Si–NBO contacts weakens such that $\text{Al}^{[4]}\text{--NBO}$ bonds form progressively for increasing CFS.

There is no experimental evidence for any significant formation of $\text{Al}^{[4]}\text{--NBO}$ bonds in Na-based aluminosilicate glasses, whereas such bonds are only encountered in $\text{CaO--Al}_2\text{O}_3\text{--SiO}_2$ glasses that are simultaneously (very) rich in both Al and Ca (Allwardt *et al.*, 2003; Cormier *et al.*, 2005); note that a high NBO content naturally boosts the $\text{Al}^{[4]}\text{--O--Al}^{[4]}$ bridges and promotes $\text{Al}^{[4]}\text{--NBO}$ bonds due to the limited number of Si–BO contacts of the depolymerized $\{Q_{\text{Si}}^n\}$ groups (Edén, 2015; Ganisetti *et al.*, 2019). Hence, it is evident that $\text{Al}^{[4]}\text{--NBO}$ motifs are energetically unstable in $\text{Na}^+/\text{Ca}^{2+}$ -based aluminosilicate glasses, as opposed to the scenario of the highly charged RE^{3+} cations in $\text{RE}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ glass networks of similar composition. The presence of $\text{Al}^{[4]}\text{--NBO}$ bonds in Si-rich and highly polymerized $\text{RE}_2\text{O}_3\text{--Al}_2\text{O}_3\text{--SiO}_2$ glasses is one example where classical MD simulations predicted a structural feature (Iftekhar *et al.*, 2012) that was only later unambiguously established experimentally (Jaworski *et al.*, 2015). Yet, the modeled $\text{Al}^{[4]}\text{--NBO}$ populations are ≈ 3 times larger (20%–40% of all NBO species) than those determined experimentally by ^{17}O NMR (7%–12%). Similar overestimations likely also apply to the very recent MD-derived predictions of the degree of Al–NBO bonding in modifier-rich $\text{CaO--Al}_2\text{O}_3\text{--SiO}_2$ (Atila *et al.*, 2019) and $\text{CaO--MgO--Al}_2\text{O}_3\text{--SiO}_2$ glasses (Ganisetti *et al.*, 2019), for which direct experimental quantifications are not available.

Borates and Borosilicates

In contrast with the SiO_2 and P_2O_5 glass formers, adding low or moderately large amounts of glass network modifier cations to B_2O_3 do not induce NBO formation, but merely leads to an increased coordination number of B. For each M^+ cation included, one planar BO_3 group converts into a $[\text{BO}_4]^-$ tetrahedron (Dell *et al.*, 1983; Wright, 2010). For $\text{M}_{(2)}\text{O--B}_2\text{O}_3\text{--}(\text{SiO}_2)$ glasses, such $\text{BO}_3 \rightarrow [\text{BO}_4]^-$ conversions prevail for increasing amount of $\text{M}_{(2)}\text{O}$, up to a content at which the fractional $\text{B}^{[4]}$ population ($x_{\text{B}}^{[4]}$) is maximized—whose precise value depends on the CFS of the modifier. For Na borate/borosilicate glasses with modest Na_2O contents and compositions parameterized as $\text{RNa}_2\text{O--B}_2\text{O}_3$ and $\text{RNa}_2\text{O--B}_2\text{O}_3\text{--KSiO}_2$, Bray and co-workers showed that $x_{\text{B}}^{[4]}(\text{max}) = R = 1/2 + K/16$ (Dell *et al.*,

Fig. 8 Fractional populations of BO_4 groups out of the $\{\text{BO}_3, \text{BO}_4\}$ speciation, as obtained either by MD simulations (squares) or NMR experiments (circles) and plotted against the ratio of molar fractions $R = x(\text{Na}_2\text{O})/x(\text{B}_2\text{O}_3)$ for (a) $\text{RNa}_2\text{O--B}_2\text{O}_3$, and (b) $\text{RNa}_2\text{O--B}_2\text{O}_3\text{--KSiO}_2$ glasses with $K = 2$. The red lines are predictions from the Yun–Dell–Bray–Xiao (YDBX) model of Dell *et al.* (1983). Data uncertainties are within/around the symbol sizes. The experimental data were selected from various literature sources, specified in the caption to Fig. 1 of [Stevansson, B., Yu, Y., Edén, M., 2018. Structure-composition trends in multicomponent borosilicate-based glasses deduced from molecular dynamics simulations with improved B–O and P–O force fields. *Phys. Chem. Chem. Phys.* 20, 8192–8209], from which the figure was modified with permission from the PCCP Owner Societies.

1983). When the Na_2O content is increased further, NBO ions are created, which are either located at the SiO_4 tetrahedra or at the BO_3 groups forming from the $[\text{BO}_4]^-$ moieties (Dell *et al.*, 1983; Wright, 2010). The alterations of $x_{\text{B}}^{[4]}$ for increasing molar-fraction ratio $R = x(\text{Na}_2\text{O})/x(\text{B}_2\text{O}_3)$ are illustrated in Fig. 8, which contrasts results from ^{11}B NMR experiments, atomistic MD simulations, and the predictions of Dell *et al.* (1983).

The $\text{BO}_3 \leftrightarrow \text{BO}_4$ conversions occurring for increasing glass-network modifier content lead to non-linear changes in the physical properties of borate/borosilicate glasses (such as the glass transition temperature and density), known in the early literature as the “boron anomaly” (Wright, 2010). Given that the glass properties are strongly related to the relative BO_3/BO_4 populations, predicting their values is of pivotal importance for the rationalization of composition–structure–property relationships in B-bearing glasses. However, the $\text{BO}_3 \rightleftharpoons \text{BO}_4$ equilibrium in the melt is temperature dependent and shifts to the right during melt-cooling, thereby elevating the BO_4 content in the glass structure relative to the melt (Sen *et al.*, 1998). This feature, coupled with the extremely rapid cooling rates of atomistic MD simulations (Section “The Cooling Rate”) and the strong glass-composition dependence of the borate speciation, present major challenges for classical MD simulations to accurately model the $\{\text{BO}_3, \text{BO}_4\}$ populations in B-bearing glasses. Successful attempts to mitigate these obstacles have been made by invoking glass-composition dependent B–O force fields (Kieu *et al.*, 2011; Inoue *et al.*, 2012; Wang *et al.*, 2018; Deng and Du, 2019), however, at the price of glass system/composition-dependent force fields with limited transferability among distinct glass systems.

Another challenge for atomistic MD simulations of borate/borosilicate glasses concerns the reproduction of “superstructural units” in the structure. Whereas the presence of such larger molecular/ionic aggregates of connected borate groups in B-bearing multicomponent glasses often lacks unambiguous experimental evidence—thereby also rendering predictions from MD simulations extremely valuable—hitherto existing force-fields exhibit significant limitations to reproduce superstructural units. One example is the fraction of boroxol rings (B_3O_6) in vitreous B_2O_3 , whose presence and amount ($\approx 70\%$) is well-established experimentally (Wright, 2010). Yet, current rigid-ion force fields used in classical MD simulations will at best predict a few percent of B as present in B_3O_6 rings. Here AIMD simulations provide much better predictions (Alderman *et al.*, 2015). Force fields that account for polarization effects of the B–O bonds offer significant improvements for enhancing the modeled boroxol fraction in B_2O_3 glass/melt (Maranas *et al.*, 2001; Zeidler *et al.*, 2014; Alderman *et al.*, 2015), as well as for reproducing the fractional populations of BO_3/BO_4 groups in borate/borosilicate glasses, as demonstrated both by shell model (Stevenson *et al.*, 2018) and PIM (Pacaud *et al.*, 2017) force fields. Yet, further developments of B–O force fields are required to improve the predicting power of atomistic MD simulations: they should combine high accuracy in their predictions of structural features with transferability among glass compositions, not only within a given system, but also among distinct glass systems.

Acknowledgments

This chapter improved significantly from discussions with, and input from, Baltzar Stevansson, whose sound expertise in computer modeling is gratefully acknowledged, as well as his assistance with some of the typesetting as well as preparation of several of the figures.

Computation of Phase Diagrams for Ceramics

Sara Serena, Angel Caballero, Antonio H de Aza, and Maria A Sainz, Institute of Ceramics and Glass-Spanish National Research Council (CSIC), Madrid, Spain

© 2021 Elsevier Inc. All rights reserved.

Introduction

Phase diagrams are used in materials science and engineering to understand the interrelationship between composition, microstructure and processing. They are graphical representations of the equilibrium state of a system as a function of constituent component concentrations (x); temperature (T) and pressure (P).

Classical methodology for determining phase diagrams is based on experimental results obtained from different dynamic and static techniques such as Differential Thermal Analysis (DTA); X-Ray Diffraction (XRD); Scanning Electron Microscopy (SEM), or Raman Spectroscopy (RAMAN) among others. However, this method is a time-consuming and costly job that becomes even tougher as the number of components increases or complex conditions (several variables, T , P , E (electric-magnetic fields)...) are considered. Thereby, while the equilibrium state of a two-component system can be represented as a binary x - T (composition-temperature at constant P) or x - P (composition-pressure at constant T); for three-components systems an additional dimension is necessary, so that they are usually represented by a series of isothermal (stable phases at each composition at constant temperature) or isoplethal sections (stable phases at a constant composition ratio of the components as a function of temperature) or liquidus surface projections as on composition plane.

On the other hand, considering that a phase diagram is the graphical representation of the thermodynamic properties of a system it can be regarded that, at least in principle, such diagrams can be calculated from thermochemical relationships and therefore find their basis of development in the thermodynamics. In practice, this is not easy due to the complexity of the process and because many of the necessary fundamental thermodynamic data for ceramics, in most cases, are not known. However, with the development of computers, it has been possible to address the treatment of multicomponent and multiphase systems using a thermodynamic approach, in which the composition of coexisting phases can be evaluated (Rao, 1970; Ansara, 1979).

The CALPHAD (CALculation of PHase Diagram) methodology has been widely developed during the past 50 years and great progress has been achieved; model descriptions have been improved and advances of the computational technology (Saunders and Miodownik, 1998; Lukas *et al.*, 2007) have allowed a better thermodynamic assessment of the systems. This method is based on the calculation of phase diagrams from mathematical descriptions of the thermodynamic properties of the phases of the system. This calculation allows reliable phase diagrams of high order systems to be obtained from constituent's subsystems that can guide experimentation and reduce the effort required to determine equilibrium. On the other hand, the difficulty of graphically representing multicomponent systems is overcome since calculations can be customized for the interest zone.

Through the years, the expression "calculation of phase diagrams" is being replaced by "computational thermodynamics" and CALPHAD is nowadays named Computer Coupling of Phase Diagrams and Thermochemistry because the phase diagram is only a portion of the information that can be obtained from these calculations. Furthermore, the recent studies of coupling phase diagrams and thermodynamic calculations with kinetic, diffusion process or microstructural models (phase field models) are enabling the thermodynamic calculations to approach more realistic work conditions of the materials and predict their chemical, physical and mechanical properties.

Nowadays, thermodynamic calculation is not an isolated field in material simulations; it is included in multi-scale modeling to accomplish optimizations of new materials and their associated processes (Wang *et al.*, 2015). These integrated projects are more advanced for metal than for ceramic systems (Yang *et al.*, 2019; Du *et al.*, 2019); but it is undoubtedly a challenge that ceramic material simulation is facing today.

Brief History of Calphad for Ceramics

Initially, the use of computational calculation methods to assemble phase diagrams and thermochemical data were applied to metallic systems (Kaufman and Nesor, 1974; Kaufman, 1977, 1979a) where the knowledge of the necessary thermodynamic data was broader than in the ceramic field. Kaufman and Bernstein (1970) gave an outline of the general features of the calculation of phase diagrams and they also gave listings of computer programs for the calculation of binary and ternary phase diagrams, thus laying the foundation for the CALPHAD method. Later, in 1973, Kaufman organized the first meeting of the international CALPHAD group. However, it was not until 1977 in the workshop on "Applications of Phase Diagrams in Metallurgy and Ceramics" held at the National Bureau of Standards in Gaithersburg (Maryland) (Carter and Bennett, 1977) when many gaps in ceramic thermodynamic data were detected and the need to develop computational methods to bridge these gaps for ceramics was noted.

Although in the 1960s there were several simple and specific applications of the use of thermodynamic data for the outline of binary phase diagrams such as: MgO-FeO (Phillips *et al.*, 1961); Al_2O_3 - Cr_2O_3 (Knapp, 1953); Al_2O_3 - ZrO_2 (Pena and De Aza, 1979);

indicating the possibilities of such procedures, it was not until the late 1970s that considerable efforts were applied toward developing an extensive database for ceramics systems. Kaufman and Nesor (1978) and Kaufman (1979b) developed a database for calculation of quasi-binary and quasi-ternary phase diagrams of ceramic systems. At the beginning, the database was restricted to a few oxides: Cr_2O_3 , MgO , FeO , Fe_2O_3 , Fe_3O_4 , Al_2O_3 , CaO , and SiO_2 , traditionally used in important industrial processes (slags, clinker, etc.). The usefulness of this approximation was illustrated by computing isothermal sections for ternary systems composed of these oxides. The above mentioned database was expanded to cover combinations of the oxides with silicon nitride, Si_3N_4 , and aluminum nitride, AlN , thus permitting computation of SiAlON or Si-Al-Zr/N-O ceramic systems (Kaufman, 1979c; Weiss *et al.*, 1981) and the development of materials with practical interest in aluminum, oil and gas industries, due to their excellent chemical stability and corrosion and wear resistance properties.

The biggest breakthrough in calculation of phase diagrams for ceramic systems took place during the nineties. The advance on the calculation methods and the development of new thermodynamic models more suitable to describe liquid and solid solution phases of oxides allowed reliable thermodynamic assessment of Al_2O_3 and/or SiO_2 containing systems among others. The first thermodynamic assessments of the systems $\text{CaO-Al}_2\text{O}_3$ and CaO-SiO_2 were made by Hallstedt (1990) and Hillert *et al.* (1990) using the CALPHAD technique and the new program PARROT for optimization of parameters. In these assessments, the liquid phase was described by a two-sublattice model for ionic solutions. Also, a thermodynamic assessment of the Si-O system (Hallstedt, 1992) was made using a two-sublattice model for ionic liquids and a regular solution model to describe the solid solution of oxygen in silicon. Afterwards, ternary systems such as $\text{CaO-MgO-Al}_2\text{O}_3$ were also assessed by Hallstedt (1995). Simultaneously, Jin and Du (1994) assessed phase diagrams and thermodynamic properties of zirconia-based systems which were of technological importance. The $\text{ZrO}_2\text{-YO}_{1.5}$ (Du *et al.*, 1991a) and $\text{ZrO}_2\text{-MgO}$ (Du and Jin, 1991b) systems were reevaluated with critically assessed Gibbs free energy functions. Furthermore, new ternary phase diagram data on the $\text{ZrO}_2\text{-YO}_{1.5}\text{-MgO}$ (Du *et al.*, 1991c) and $\text{ZrO}_2\text{-YO}_{1.5}\text{-CaO}$ (Du and Jin, 1992a) systems were published. The same authors carried out the thermodynamic evaluation of the $\text{ZrO}_2\text{-CaO-MgO}$ (Du *et al.*, 1992b) system combining the previous descriptions of the binary subsystems by means of Bonnier and Caboz's extrapolation (Bonnier and Caboz, 1960). Calculation of nitrogen or carbon containing systems such as: Si-Al-O-N (Hillert and Jonsson, 1992; Dumitrescu and Sundman, 1995); Si-C-N (Seifert *et al.*, 2001) and Al-C-N-Si-O (Pavlyuchkov *et al.*, 2012) was also addressed in this time-frame. These systems are useful for developing refractories and components in latest generation of engines or gas turbines, where mechanical engineering devices and components are designed to work at high temperatures.

From the late 1990s up to the present, calculation of new phase diagrams for ceramics with more oxide and non-oxide components have been addressed, covering a range of materials from classic refractory, slags or clinker materials to advanced ceramics. Important applications can be found in diverse fields such as $\text{ZrO}_2\text{-TiO}_2$ or BaO-TiO_2 quasibinary systems (Gong *et al.*, 2001; Xiaogang and Zhanpeng, 2000) for electroceramics, $\text{Na}_2\text{O-Al}_2\text{O}_3\text{-SiO}_2\text{-B}_2\text{O}_3$ (Utlak and Besmann, 2019) for development of nuclear waste, $\text{ZrO}_2\text{-HfO}_2$ (Wang *et al.*, 2006) system for thermal barrier coatings or solid oxide fuel cells, Si-C-Al-Y-O (Pan *et al.*, 2010) to improve SiC -based engineering ceramics or $\text{SrO-Al}_2\text{O}_3\text{-SiO}_2$ system for environmental barrier coating and prediction of SiC recession caused by SiO_2 volatility under combustion environments (Zhang *et al.*, 2014). Some of the most recent assessments are related to P_2O_5 -based systems with important applications as phosphate bioceramics and/or in steelmaking industries among others, such as the $\text{CaO-P}_2\text{O}_5$ (Serena *et al.*, 2011) and $\text{CaO-P}_2\text{O}_5\text{-SiO}_2\text{-ZnO}$ (Jantzen *et al.*, 2019) systems.

From the beginning, thermodynamic calculation has been a very dynamic investigation field, new models and calculations methods have been developed, different systems have been constantly calculated or reassessed based on recent experimental data or new thermodynamic descriptions, and simulations of complex physicochemical processes have been addressed through the years.

The development of advanced thermodynamic software accessible to the general user and generalist and multicomponent databases confirm that CALPHAD is in fact a powerful tool increasingly used in recent years to explain multiple behaviors of ceramic materials in processes of technological interest.

Calphad Methodology

The aim of the CALPHAD method is to obtain a description of the phase diagram and thermodynamic properties to reliably predict the set of stable phases even in regions without experimental information. For this, the Gibbs energy of each phase must be calculated and then, equilibrium conditions can be established based on the minimization of the free energy of the system.

The most used state function for thermodynamic modeling is the Gibbs energy (G) which is a function of T , P and the components (N_i):

$$G = G(T, P, N_i, \dots) \quad (1)$$

When a process takes place, Gibbs free energy change (ΔG) is given by:

$$\Delta G = \Delta U + P\Delta V - T\Delta S \quad (2)$$

where U is the internal energy and S is the entropy and V is the volume. For a process at constant pressure ΔG is written as:

$$\Delta G = \Delta H - T\Delta S \quad (3)$$

where H is the enthalpy.

Fig. 1 Flow chart of the sequential steps in thermodynamic calculation for multicomponent systems.

Correlation between thermodynamics and phase equilibria in a multicomponent system is established on the basis of minimum Gibbs energy criteria for the system:

$$G = \sum_{\varphi} n^{\varphi} \cdot G_m^{\varphi} = \text{minimum} \quad (4)$$

where G_m^{φ} and n^{φ} are the molar Gibbs energy and the number of moles of phase φ respectively.

Considering this, in equilibrium conditions at T , P and N_i , the Gibbs energy has a minimum. dG can be expressed as:

$$dG = \left(\frac{\partial G}{\partial T} \right)_{P, N_i} dT + \left(\frac{\partial G}{\partial P} \right)_{T, N_i} dP + \left(\frac{\partial G}{\partial N_i} \right)_{T, P} dN_i \quad (5)$$

From the derivation of the Gibbs energy the following relationships are established:

$$S = - \left(\frac{\partial G}{\partial T} \right)_{P, N_i} ; \quad V = \left(\frac{\partial G}{\partial P} \right)_{T, N_i} ; \quad \mu_i = \left(\frac{\partial G}{\partial N_i} \right)_{T, P} \quad (6)$$

where μ_i is the chemical potential of component i .

A schematic CALPHAD route for calculating phase diagrams is shown in **Fig. 1**. First, the existing information is collected including both experimental results and data from *ab initio* or *first-principle* calculations. Second, Gibbs energy of each phase, attending to its chemical-physical properties, is described with a mathematical model containing adjustable parameters. Third, these parameters are evaluated by optimizing the fit of the model for all the collected information related to the system such as phase stability relationships and thermochemical and thermophysical studies of the phases. Finally, the results of equilibrium calculation can be represented in a graphical form.

Once databases have been developed, consistent and reliable phase diagrams can be calculated on the basis of thermodynamic equilibrium relationships.

Experimental Data and *ab initio* Calculation

Calculation of phase diagram by the CALPHAD approach needs a basic amount of experimental data to develop robust, consistent and reliable thermodynamic databases. The experimental measurements can be classified as "Structural data", "Phase-diagram data" and "Thermodynamic data".

Structural data are crystalline structure of the phases, ordering in solid and liquid phases. The most used techniques for determining the crystalline structure in ceramic systems are: X-ray Diffraction (XRD); Infrared Spectroscopy (IR) and Nuclear Magnetic Resonance (NMR).

Phase diagram data are obtained from isothermal and dynamic methods.

The aim of isothermal methods is to characterize the phases appearing in the material in equilibrium conditions so that samples are subjected to long time thermal treatments to ensure equilibrium has been reached. This is especially complex in ceramics because of high temperatures and remilling processes are sometimes needed to reach homogeneity and equilibrium conditions. The quench technique accompanied by characterization is still the best and most accurate way to determine a phase equilibria diagram. Phase stabilities and compatibility relationships can be established from microscopy techniques such as

optical and scanning electron microscopy with EPMA (Electron Probe Microanalysis). Mineralogical characterization is also essential in ceramics in terms of X-ray diffraction techniques.

Phase boundaries can be determined from non-isothermal techniques observing the evolution of a specific quantity as a function of temperature cycles for a determined composition. The preferred method for dynamic equilibria analyses is in-situ high-temperature XRD. Other techniques to establish energy or temperature variations in the sample are DTA, Differential Scanning Calorimetry (DSC); Electromotive Force Measurement (EFM) techniques in non-isothermal conditions and changes in magnetic susceptibility or resistivity while cooling or heating the sample.

All this information, such as equilibrium phases, phase quantity, phase composition, phase boundaries and temperature and composition of invariant points can be used to determine phase equilibrium diagrams.

Thermodynamic data for H , S and C_p can be obtained from calorimetric methods; activity ($a_i = p_i/p_0$) values from gas/phase equilibria measurements through static and dynamic conditions; chemical potential μ_i can be obtained from EFM using the Nernst equation.

In order to describe the contribution of pressure to the Gibbs energy, the measurement of bulk modulus, thermal expansion or elastic constants as a function of pressure and temperature are needed.

Another set of data comes from so-called *ab initio* or *first-principle* calculations, devoted to directly solve the Schrödinger equation and obtain the wave functions of quantum mechanics for the desired system (Liu, 2009). This approach provides a consistent description of both thermodynamic and thermophysical properties of a compound in gaseous, liquid or solid state using several parameters having physical meanings.

To carry out *ab initio* calculations it is necessary to know the atomic species and crystal structure of the compound, then, quantities related to the electronic structure and total energy of a given structure can be obtained. In short, Gibbs energy of a solid phase can be calculated expressing it as the summation:

$$G(T, P) = E^{\text{tot}} + F^{\text{trans}} + F^{\text{rot}} + F^{\text{vib}} + F^{\text{conf}} + PV \quad (7)$$

Being E^{tot} total electronic energy, F^{trans} and F^{rot} translational and rotational free energy, respectively, F^{vib} vibrational free energy, F^{conf} conformational free energy and PV the expansion term, for a specific compound and crystalline structure. Each term can be calculated in the frame of different approximations. Afterwards, enthalpy, entropy and heat capacity functions can be obtained applying classical thermodynamic relationships.

Several *ab initio* molecular dynamics software packages have been developed for calculating and simulating properties of a wide range of materials or liquid phases.

Thermodynamic Modeling

The CALPHAD method employs a variety of models to describe the temperature, pressure and concentration dependencies of the Gibbs functions of the phases. Specifically, the aim is to obtain an expression for G including parameters to be optimized in terms of experimental data. The selection of the model should be based on its physical and chemical properties, for example, crystallography, type of bonding, order in solid solutions or liquid phases, or magnetic aspects. Nevertheless, the last objective is to develop generalist and consistent databases so the simplicity of the model should also be considered.

The more general expression for the Gibbs energy of a phase (G^ϕ) can be described as:

$$G^\phi = G_T^\phi(T, x) + G_P^\phi(P, T, x) + G_M^\phi(T_C, \beta_0, T, x) \quad (8)$$

where $G_T^\phi(T, x)$ is the contribution to the Gibbs energy of T and x (composition) and $G_P^\phi(P, T, x)$ is the contribution of P while $G_M^\phi(T_C, \beta_0, T, x)$ is the magnetic contribution of the Curie (T_C) or Néel temperature (T_N) and the average magnetic moment per atom (β_0).

Temperature dependence of Gibbs free energy

Omitting magnetic contributions, thermodynamic functions of the different stable phases of elements and stoichiometric compounds only depends on temperature and pressure.

Attending to the recommendation of the Scientific Group Thermodata Europe (SGTE), at constant pressure, Gibbs energy can be expressed as a sum of terms:

$$G_i - H_i^{\text{SER}}(298.15\text{K}) = a + bT + cT \ln T + dT^2 + eT^{-1} + fT^3 + \dots \quad (9)$$

where $H_i^{\text{SER}}(298.15\text{K})$ is the molar enthalpy of the element i at 298.15 K in its standard state and a , b , c , ... are adjustable parameters.

Gibbs energy can be obtained from $C_p(T)$ functions, $\Delta H_{298.15}$ and $\Delta S_{298.15}$ (standard enthalpy and entropy of formation respectively) by the equations:

$$\Delta H_T = \Delta H_{298.15} + \int_{298.15}^T C_p \, dT; \Delta S_T = \Delta S_{298.15} + \int_{298.15}^T \frac{C_p}{T} \, dT \quad (10)$$

$$\Delta G_T = \Delta H_{298.15} + \int_{298.15}^T C_p \, dT - T \left(\Delta S_{298.15} + \int_{298.15}^T \frac{C_p}{T} \, dT \right) \quad (11)$$

Values for C_p , $\Delta H_{298.15}$ and $\Delta S_{298.15}$ of stoichiometric compounds are collected in thermodynamic databases (See Section on "Calculation Software Packages").

Pressure dependence of Gibbs free energy

Pressure affects the properties and phase stability of gaseous and condensed phases, especially at high pressure and temperature, but this dependence is often omitted in the thermodynamic modeling of condensed phases. In ceramic phases, molar volume (V_m) changes can be very important in some phase transitions and it is fundamental to know this to obtain the volume fraction of a phase.

The effect of P on Gibbs energy is given by the well known relationship:

$$G_P^\phi(P, T) = \int V_m dP \quad (12)$$

so that, a state equation $V(T, P)$ of a phase must be established in terms of the proper thermodynamic model.

In a first approximation, the ideal gas equation of state can be applied to a gaseous phase:

$$PV = nRT \quad (13)$$

so that Gibbs energy is established by:

$$G^{gas}(p_f) = {}^oG_{gas} + nRT \ln\left(\frac{p_f}{p_o}\right) \quad (14)$$

However, defining a state equation for condensed phases is a complex question. Although several relationships have been proposed based on different theoretical assumptions, their ability to extrapolate the behavior of solids at high pressure is sometimes questionable and none of them is valid for the entire range of T and P . This situation became even more complex when modeling solution phases, so that the application of CALPHAD at high pressures is unresolved.

The relationship between the volume (V) of a body and the pressure (P) to which it is subjected is given by the equation:

$$K = -V \left(\frac{\partial P}{\partial V} \right)_T \quad (15)$$

where K is the bulk modulus.

The classical approach proposed by Murnaghan is that the bulk modulus is a linear function of pressure (Murnaghan, 1944). This model is useful in limited pressure ranges but it is used nowadays as a first approach. An example of application of different state functions to oxides (forsterite Mg_2SiO_4) has been developed by Jacobs and Oonk (2001). A new pressure-dependent model was proposed by Lu *et al.* (2005) which includes composition dependent parameters in the modeling of solution phases.

Attending to the recommendation of the SGTE, pressure dependent contribution $G_P^\phi(P, T)$ for condensed phases is expressed in the form of the Murnaghan equation:

$$G_P^\phi(P, T) = \frac{A \exp(a_0 T + a_1 T^2/2 + a_2 T^3/3 + a_3 T^{-1})}{(K_0 + K_1 T + K_2 T^2)(n-1)} \left[(1 + nP(K_0 + K_1 T + K_2 T^2))^{1-1/n} - 1 \right] \quad (16)$$

where A , a_0 , a_1 , a_2 and a_3 , K_0 , K_1 and K_2 , and n are constants for a particular element and phase. Taking into account the well know relationships:

$$V_m = \left(\frac{\partial G}{\partial P} \right)_T; \quad \alpha = \frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_T; \quad \kappa = -\frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_T \quad (17)$$

where α is the expansivity and κ is the compressibility, it can be seen from the above Eq. (16) that the parameter A is equivalent to the molar volume of the material at 0 K and 0 Pa. Furthermore, the parameters a_0 , a_1 , a_2 and a_3 represent the thermal expansibility of the material as a function of temperature for a pressure of 0 Pa. In an equivalent way, the parameters K_0 , K_1 , and K_2 represent the variation of the compressibility with temperature at zero pressure.

Compositional dependence of Gibbs free energy of multicomponent solution phases

Dependence of the Gibbs energy with composition is the core of the CALPHAD method. Rarely do the calculations involve purely stoichiometric compounds and solution phases.

Gibbs energy of stoichiometric compounds can be calculated from the stoichiometric contribution of the components at the corresponding reference state (oG_i) and the Gibbs energy of formation ($\Delta^f G^\phi$), thus for a binary stoichiometric phase (A_aB_b):

$$G^\phi = x_A {}^oG_A + x_B {}^oG_B + \Delta^f G^\phi \quad (18)$$

where x_A and x_B are mole fractions of components A and B given by the compound stoichiometry.

For solution phases, compositional dependence of the Gibbs energy can be expressed as the general equation:

$$G^\phi = {}^{ref}G_{mix}^\phi + {}^{ideal}G_{mix}^\phi + {}^{xs}G_{mix}^\phi \quad (19)$$

where the contribution of the pure components is ${}^{ref}G_{mix}^\phi$ while ${}^{ideal}G_{mix}^\phi$ is the ideal mixing contribution and finally ${}^{xs}G_{mix}^\phi$ is the contribution due to the non-ideal interactions between the components (excess Gibbs energy).

The contribution of the pure components (i) of a phase, to the Gibbs energy of a solution is given by:

$${}^{ref}G_{mix}^\phi = \sum_i x_i {}^oG_i^\phi \quad (20)$$

being x_i the constituents of the phase.

It is important to note that the term ${}^{\circ}G_i^{\phi}$ is the Gibbs energy of the component i in the solution phase even though it may not be as stable as the considered phase. The relative Gibbs energy for various phases of the metastable states of pure components of the system, referred to as "lattice stabilities" can be defined as a reference state. Then, ${}^{\circ}G_I^{\phi}$ means the Gibbs energy of formation of the constituent array I in ϕ from the reference state of the elements (i, j) included in the constituents and is a function of T and P :

$${}^{\circ}G_I^{\phi} - \sum_k b_{ij} H_j^{REF} = f(T, P) \quad (21)$$

Gibbs energy of a multicomponent phase can be attributed to two main factors: the bonding between the constituents and their configuration. The configurational part always enhances the mixing of unlike atoms. The bond energy between two unlike atoms may be either more negative than the bond energy between two equal atoms (creating a tendency for compound formation or ordering) or more positive (creating a tendency for there to be a miscibility gap).

Thermodynamic models for ceramic systems

The first models used to describe solution phases were based on the random mixture of components. Afterward, models considering the existence of some kind of order in the structure of the solutions were developed. This was especially relevant in the modeling of both liquid and solid solution phases in oxide and non-oxide ceramic systems. In fact, the behavior of SiO_2 , Al_2O_3 or B_2O_3 melts prompted the development of new liquid models to address the non-continuous behavior observed in the thermodynamic properties of these phases. Several models were developed to include the short ordering observed in liquids, as cellular models, modified quasichemical models, sublattice models, and associated solution models. Sublattice models are nowadays the most used in ceramic solid solutions modeling.

There are many models to simulate solution phases (Saunders and Miodownik, 1998; Lukas *et al.*, 2007) and to illustrate this some of the more commonly used in ceramic systems are described below.

Random substitutional models

These were the first proposed models for describing binary solutions and have been used in several ceramic systems. Random models can be applied to describe solid solutions where the constituents have the same probability of occupying any site in the crystalline unit cell and liquid phases.

In this case, ideal mixing contribution to Gibbs energy is given by:

$${}^{ideal}G_{mix}^{\phi} = -T^{ideal}S_{mix}^{\phi} = RT \sum_{i=1}^n x_i \cdot \ln(x_i) \quad (22)$$

so that, from Eq. (19), the molar Gibbs energy of a solution with n components, can be calculated:

$$G_m^{\phi} = \sum_{i=1}^n x_i \cdot {}^{\circ}G_i^{\phi} + RT \sum_{i=1}^n x_i \cdot \ln(x_i) + {}^{xs}G_{mix}^{\phi} \quad (23)$$

Deviation from the ideal behavior is considered in the excess Gibbs energy and several specific cases can be distinguished:

- (1) An ideal solution is characterized by the random distribution of non-interacting constituent so that ${}^{xs}G_{mix}^{\phi} = 0$. The mixing Gibbs energy is thus dependent only on the configurational entropy:

$$G_m^{\phi} = \sum_{i=1}^n x_i \cdot {}^{\circ}G_i^{\phi} + RT \sum_{i=1}^n x_i \cdot \ln(x_i) \quad (24)$$

The ideal model is applied to describe diluted solutions and ideal solutions.

- (2) For solution phases with significant interaction between constituents, ${}^{xs}G_{mix}^{\phi}$ can be described in terms of a Redlich–Kister power series (Redlich and Kister, 1948) of interaction parameters ${}^vL_{ij}$:

$${}^{xs}G_{mix}^{\phi} = \sum_{i=1}^{n-1} \sum_{j=i+1}^n x_i x_j L_{ij}; \quad L_{ij} = \sum_{v=0}^k (x_i - x_j)^v \cdot {}^vL_{ij} \quad (25)$$

Being ${}^vL_{ij}$ temperature dependent: ${}^vL_{ij} = {}^v a_{ij} + {}^v b_{ij} T$

For $v = 0$, the equation gives just a single interaction parameter for the phase in the binary i - j system so the interaction is constant with composition (*regular solution model*). For $v \geq 1$ this leads to the *subregular solution model* where interaction energies are considered to change linearly with compositions.

A typical example of application of random substitutional models to ceramics is the MgO–CaO system. The structural studies on the MgO–CaO solid phases clearly show that Mg^{2+} and Ca^{2+} can replace each other in the corresponding lattice. Both MgO and CaO adopt a cubic structure so that solid solutions can be described as a unique structure: Halite, representing both MgO-rich (Halite-MgO) and CaO-rich (Halite-CaO) solid solution phases (Fig. 2). Likewise, no order is observed in the liquid phase so that this model can be also applied to this phase.

Fig. 2 Crystal structure of Halite phase (*Fd3m*) (a) Halite-CaO and (b) Halite-MgO, (c) Calculated phase equilibrium diagram of the CaO-MgO system.

Associate species solution models

These models were developed to describe solution phases when the equilibria cannot be represented with only species of the same stoichiometry as the end-members (Pelton and Kang, 2007). Typically, associate species solution models are applied when a sharp minimum is observed in the thermodynamic properties (as enthalpy of formation of the phase) at a defined composition. This behavior can be related to the presence of short-range order in the solution phase around singular compositions. When applied to liquid phases, the short-range order is comprised in the model defining intermediate “chemical species” or associates formed inside the liquid from reaction between the components of the system. This reduces the configurational entropy so that their corresponding thermodynamic data represent the negative, non-ideal mixing of the end-member components in the system. The thermodynamic properties of the liquid depend predominantly on the Gibbs energy of formation of these complexes; nevertheless, the interaction between chemical species was further considered in the modified associate solution model.

Considering the formation of a single associate with a formula A_iB_j in a binary system A-B, that liquid can contain n_A and n_B moles of A and B in equilibrium with $m_{A_iB_j}$ moles of the single associate A_iB_j . Then, ${}^{xs}G^\phi$

$${}^{xs}G^\phi = G_{asso}^\phi + G_{regular\ mix}^\phi \quad (26)$$

where G_{asso}^ϕ is the Gibbs energy of formation of an associate, defined as:

$$G_{asso}^\phi = m_{A_iB_j} {}^\circ G_{A_iB_j}^\phi \quad (27)$$

Being ${}^\circ G_{A_iB_j}^\phi$ the energy of formation of one mole of the associate and $G_{regular\ mix}^\phi$ considers the Gibbs energy due to the interactions between the components A and B themselves and with the associate A_iB_j such that

$$G_{regular\ mix}^\phi = G_{A,B}^\phi \frac{n_A n_B}{n} + G_{A,A_iB_j}^\phi \frac{n_A A_i B_j}{n} + G_{B,A_iB_j}^\phi \frac{n_B A_i B_j}{n} \quad (28)$$

$$S_{conf\ mix}^\phi = -R(n_A \ln(x_A) + n_B \ln(x_B) + n_{A_iB_j} \ln(x_{A_iB_j})) \quad (29)$$

${}^\circ G_{A_iB_j}^\phi$ and the interaction parameters can be used to fit experimental data.

This model has been used to describe the thermodynamic properties of liquid phases in several oxide ceramic systems (Besmann and Spear, 2002). As an example, to describe the liquid phase in the $\text{Na}_2\text{O}-\text{Al}_2\text{O}_3$ binary oxide system, it is necessary to consider an ideal liquid solution phase from end-member liquid components Na_2O (liquid) and Al_2O_3 (liquid); and intermediate associate species NaAlO_2 (liquid) and $\text{Na}_2\text{Al}_4\text{O}_7$ (liquid). The NaAlO_2 associate specie appears in the system as a crystalline phase, while the $\text{Na}_2\text{Al}_4\text{O}_7$ specie has no crystalline corresponding phase but it is necessary to accurately reproduce the phase relations in the compositional region near $\text{Na}_2\text{O}:\text{Al}_2\text{O}_3 = 1:2$.

Modified quasichemical model

This model was developed to consider short range order (SRO) in oxide liquids but it can be also applied to solid solutions as a special case, when the number of lattice sites and coordination numbers are constant.

The modified quasichemical model (Pelton and Wu, 1999) considers that liquid has a strong tendency to order around specific compositions, associated with specific physical phenomena.

Atoms or molecules of the N components of the solutions are distributed over the sites of a quasi-lattice. In the pair approximation, we consider the pair-exchange reactions:

$$(m - m) + (n - n) = 2(m - n); \quad \Delta g_{mn} \quad (30)$$

where m and n are $1, 2, \dots, N$; and $(m - m)$, $(n - n)$ and $(m - n)$ represent first-nearest-neighbor pairs. The non-configurational Gibbs energy change for the formation of two moles of $(m - n)$ pairs is Δg_{mn} .

$$G = \sum n_m g_m^o - T\Delta S^{\text{config}} + \sum_{m>n} n_{mn} (\Delta g_{mn}/2) \quad (31)$$

where g_m^o is the molar Gibbs energy of pure component m , and ΔS^{config} is an approximate expression for the configurational entropy of mixing, given by randomly mixing the $(m - n)$ pairs:

$$\Delta S^{\text{config}} = -R \sum n_m \ln(X_m) - R \left(\sum n_m \ln(X_m/Y_m^2) + \sum_{m>n} n_{mn} \ln(X_m/2Y_m Y_n) \right) \quad (32)$$

where X_m is the pair fraction and Y_m coordination-equivalent fraction.

$$\Delta g_m = \Delta g_m^o + \sum_{i>1} {}^i L_{mn} (Y_m - Y_n)^i \quad (33)$$

Δg_m^o and ${}^i L_{mn}$ are empirical binary parameters to be optimized from experimental data.

This model has been used in thermodynamic assessment of several ceramic systems such as MgO–Al₂O₃, CaO–MgO–Al₂O₃, and MgO–Al₂O₃–SiO₂ (Jung *et al.*, 2004) and it is included in different powerful databases for multicomponent systems.

Sublattice models

The most complex and general model applied nowadays to solid solutions is the sublattice model (Sundman and Ågren, 1981). In crystalline solids the atoms may occupy different types of sublattices with different coordination numbers, bond lengths, etc. A solid phase can be seen as a mixture of interlocking sublattices on which various components can mix randomly. In nature the model does not define any crystal structure within its general mathematical formulation, although it is possible to define internal parameter relationships, which reflect structure with respect to different crystal types.

One simple case of a sublattice model would be two-sublattices with several constituents in each sublattice. A shorthand notation of this would be:

$$(A, B, \dots)_a (U, V, W, \dots)_c \quad (34)$$

where the subscripts a and b give the ratio of sites on the two sublattices. The constituents $A, B, \dots, U, V$ can represent atoms, ions, anti-site atoms, vacancies, etc.

Considering the general Eq. (19); the Gibbs energy for the two sublattice model is:

$$G_m^\phi = \sum_i \sum_j \gamma_i' \gamma_j'' \text{Ref } G_{ij}^\phi + RT \left(a \sum_i \gamma_i' \ln(\gamma_i') + b \sum_j \gamma_j'' \ln(\gamma_j'') \right) + {}^{xs} G_m^\phi \quad (35)$$

where γ_i' and γ_j'' are the constituent fractions on sublattices 1 and 2, respectively. The term $\text{Ref } G_{ij}^\phi$ is the Gibbs energy of the phase ϕ when only one pure component exists on each sublattice and then a reference energy surface is defined.

For two components in each sublattice $(A, B)_m (C, D)_n$, considering a random mixture of the species in a sublattice, ${}^{xs} G_m^\phi$ can be written as:

$${}^{xs} G_m^\phi = \gamma_A' \gamma_B' \gamma_C'' \gamma_D'' L_{AB:C} + \gamma_A' \gamma_B' \gamma_D'' \gamma_C'' L_{AB:D} + \gamma_A' \gamma_C' \gamma_D'' \gamma_B'' L_{A:CD} + \gamma_B' \gamma_C' \gamma_D'' \gamma_A'' L_{B:CD} + \gamma_A' \gamma_B' \gamma_C'' \gamma_D'' L_{AB:CD} \quad (36)$$

In this expression, there are two interaction parameters for each sublattice depending on the constituent on the other sublattice. The binary interaction parameters can be expanded as a Redlich-Kister polynomial.

This model has been widely applied to describe solid solution phases in oxide and non-oxide ceramic systems. An illustrative example is spinel structures such as MgAl₂O₄-spinel (Ma and Liu, 2019) which is usually assigned to the cubic space group $Fd\bar{3}m$. It is formed as an approximately cubic, close-packed array of oxygen atoms, between which are tetrahedral T-sites and octahedral O-sites (Fig. 3). Some thermodynamic assessments describe a spinel solution within the framework of the two-sublattices compound energy formalism (Jung *et al.*, 2004) modeling it as:

$$(Mg^{2+}, Al^{3+})^T (Mg^{2+}, Al^{3+}, Va)_2 O_4 \quad (37)$$

with $m = 1$ and $n = 2$ sites on the tetrahedral and octahedral sublattices, respectively. Non-stoichiometry can occur through the introduction of vacancies, Va , on octahedral sites.

Ionic two-sublattice models for ionic liquids

This model is an extension of the sublattice model that has been widely used to describe the thermodynamic properties of liquid phases in ceramic systems (Sundman, 1991).

This model addresses short range order (SRO) in liquids considering that the structure can be described as two sublattices, with anionic, cationic, and neutral species. This does not mean the existence of fixed sites in space but a complete separation of cations in one sublattice, and anions, vacancies and neutral species in the other. The sublattice formula for the model can then be written as:

Fig. 3 (a) Crystal structure of MgAl₂O₄-spinel phase. (b) Calculated phase equilibrium diagram of the MgO-Al₂O₃ system.

$$(C_i^{+v_i})_P (A_j^{-v_j}, Va, B_k^0)_Q \quad (38)$$

where C represents cations, A anions, Va hypothetical vacancies and B neutral species. The charge of an ion is denoted as v_i and the indices i , j and k are used to denote specific constituents. To simplify, the notation superscripts v_i , v_j and 0 will be omitted in the following. The number of sites on the sublattices is varied so that electroneutrality is maintained and values of P and Q are calculated from the equation:

$$P = \sum_j v_j \cdot \gamma_{A_j} + Q \gamma_{Va}; \quad Q = \sum_i v_i \cdot \gamma_{C_i} \quad (39)$$

where P and Q are stoichiometric numbers that vary with the composition to maintain electroneutrality.

Taking into account the above, the total Gibbs energy of the liquid phase is given by:

$$\begin{aligned} G_M^{\text{Liquid}} - H^{\text{SER}} = & \sum_i \sum_j \gamma_{C_i} \gamma_{A_i}^{\text{Ref}} G_{C_i A_i}^{\text{Liquid}} + Q \gamma_{Va} \sum_k \gamma_{C_i}^o G_{C_i}^{\text{Liquid}} + Q \sum_k \gamma_{B_i}^o G_{B_i}^{\text{Liquid}} \\ & + RT \left[P \sum_i \gamma_{C_i} \log_e \gamma_{C_i} + Q \left(\sum_j \gamma_{A_j} \log_e \gamma_{A_j} + \gamma_{Va} \log_e \gamma_{Va} + \sum_k \gamma_{B_k} \log_e \gamma_{B_k} \right) \right] + {}^{\text{xs}}G_m^{\text{Liquid}} \end{aligned} \quad (40)$$

By considering the general expression (25) ${}^{\text{xs}}G_m$ can be written as:

$$\begin{aligned} {}^{\text{xs}}G_m = & \sum_{i_1} \sum_{i_2} \sum_j \gamma_{i_1} \gamma_{i_2} \gamma_j \cdot L_{i_1 i_2 j} + \sum_{i_1} \sum_{i_2} \gamma_{i_1} \gamma_{i_2} \gamma_{Va} \cdot L_{i_1 i_2 Va} + \sum_{i_1} \sum_{j_1} \sum_{j_2} \gamma_{i_1} \gamma_{j_1} \gamma_{j_2} \cdot L_{i_1 j_1 j_2} + \sum_i \sum_j \gamma_i \gamma_j \gamma_{Va} \cdot L_{ij Va} \\ & + \sum_i \sum_j \sum_k \gamma_i \gamma_j \gamma_k \cdot L_{ijk} + \sum_i \sum_k \gamma_i \gamma_j \gamma_{Va} \cdot L_{i Va k} + \sum_{k_1} \sum_{k_2} \gamma_{k_1} \gamma_{k_2} \cdot L_{k_1 k_2} \end{aligned} \quad (41)$$

where ${}^oG_{C_i A_i}^{\text{Liquid}}$ is the Gibbs energy of formation for $(v_i + v_2)$ moles of atoms of liquid $C_i : A_i$ and ${}^oG_{C_i}^{\text{Liquid}}$ and ${}^oG_{B_i}^{\text{Liquid}}$ are the Gibbs energy of formation per mol of atoms of liquid C_i and B_i . In this expression, there are interaction parameters between species in each sublattice depending on the constituent in the other sublattice, which can be expanded as a Redlich-Kister polynomial.

This model has been widely used in oxide and non-oxide ceramic systems from the beginning. One of the most significant applications is the description of melts in glass forming systems such as silicates. Silicate glasses are the typical representatives of the covalently bonded glasses and their structure is well described by the continuous random network model (Osipov and Osipova, 2013) as a continuous network of SiO₄ tetrahedra randomly interconnected via the oxygen apexes. One example is the thermodynamic assessment of the CaO-SiO₂ system provided by Mao *et al.* (2006) in which the liquid was described with the formula:

$$(Ca^{2+})_P (O^{2-}, SiO_4^{4-}, SiO_2^0)_Q \quad (42)$$

where the SiO_2^0 species represents the tetrahedral network of pure liquid silica, and the mixture of the SiO_4^{4-} and SiO_2^0 species represent the variable polymerization degree in compositions between Ca_2SiO_4 and SiO_2 . In the case of $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ the expression is:

$$(\text{Al}^{3+}, \text{Ca}^{2+})_P (\text{AlO}_2^-, \text{O}^{2-}, \text{SiO}_4^{4-}, \text{SiO}_2^0)_Q \quad (43)$$

Optimization of Parameters

Thermodynamic optimization can be considered as the fitting of certain parameters of Gibbs energy functions in order to obtain the most realistic representation of experimental studies of phase diagrams and available thermodynamic properties of the system. These parameters are determined by optimizing the fit of the model to all the experimental and theoretical information collected about the system (See Section on “Experimental Data and *ab initio* Calculation”). To ensure a reliable calculation that allows the extrapolation to high order systems, all experimental information must be critically analyzed to identify the less reliable data and discard possible erroneous data.

There are “optimizer” codes, which are used for the thermodynamic assessment of phase equilibria. The essential aim of these codes is to reduce the statistical error between calculated phase equilibria, thermodynamic properties and the equivalent measured quantities. The accuracy can be mathematically defined through some optimization software. The Lukas program and PARROT program are the main codes currently used for minimization. The aim in both cases is reduction of the error between calculated and experimental variables.

The Lukas program uses a Gaussian least-squares method (Lukas *et al.*, 1977). Equations of error are given for each type of measurement: (1) Calorimetric measurements, which are usually enthalpies, (2) EMF and vapor pressure which provide partial G and c) phase diagram information.

In the PARROT program (Jansson, 1984) the criterion for best fit is based on the maximum likelihood principle, where the best estimate of the model parameters should maximize the likelihood function for the different experimental observations. The best fit between various calculated results and all the input of experimental data is found where the sum of the squares of the weighted residuals is at its minimum.

Extrapolation of the Gibbs Energy to Higher Order Systems

Extrapolation to multicomponent systems is one of the main objectives of the CALPHAD methodology. Several “geometric” models have been proposed to estimate thermodynamic properties of a ternary solution from optimized data of its binary subsystems. The most common are the Muggianu *et al.* (1975), Kohler (1960) and Toop (1965) models. Attending to the geometrical representation (Fig. 4; it can be seen that the Muggianu and Kohler equations are considered “symmetric” as they treat the components in the same way. On the contrary, the Toop model is “asymmetric” since one component is singled out.

In short, the contribution of binary excess Gibbs energies ($^{xs}G_{ij}^{q-bin}$) to the total molar ternary excess Gibbs energy ($^{xs}G_m^{q-ter}$) is given by:

$$^{xs}G_m^{q-ter} = \sum_{i,j} w_{ij} \cdot ^{xs}G_{ij}^{q-bin} \quad (44)$$

where the binary weighting factor, w_{ij} , depends on the geometric model selected.

In symmetric models the weighting factor is equivalent for the three binary systems, while in the asymmetric model the contribution of each binary system can be different.

Considering that a subregular substitutional solution model (Eqs. 19–21) has been used to describe the binary phases, $^{xs}G_m^{q-ter}$ applying the Muggianu model is given by the equation:

$$^{xs}G_m^{q-ter} = x_A x_B [{}^0L_{AB} + {}^1L_{AB}(x_A - x_B)] + x_B x_C [{}^0L_{BC} + {}^1L_{BC}(x_B - x_C)] + x_A x_C [{}^0L_{AC} + {}^1L_{AC}(x_A - x_C)] \quad (45)$$

Fig. 4 Geometrical representation of classical extrapolation methods. (a) Muggianu, (b) Kohler and (c) Toop models.

If the Kohler model is applied to the extrapolation then:

$$^{xs}G_m^{\varphi-ter} = x_A x_B \left[{}^0L_{AB} + {}^1L_{AB} \left(\frac{x_A - x_B}{x_A + x_B} \right) \right] + x_B x_C \left[{}^0L_{BC} + {}^1L_{BC} \left(\frac{x_B - x_C}{x_B + x_C} \right) \right] + x_A x_C \left[{}^0L_{AC} + {}^1L_{AC} \left(\frac{x_A - x_C}{x_A + x_C} \right) \right] \quad (46)$$

When the Toop model is used, Gibbs energy of the ternary solution is essentially different because the contribution of one binary system B – C is different:

$$^{xs}G_m^{\varphi-ter} = x_A x_B \left[{}^0L_{AB} + {}^1L_{AB} (x_A - x_B - x_C) \right] + x_A x_C \left[{}^0L_{AC} + {}^1L_{AC} (x_A - x_C - x_B) \right] + x_B x_C \left[{}^0L_{BC} + {}^1L_{BC} \left(x_B - x_C + \frac{x_B - x_C}{x_B + x_C} x_A \right) \right] \quad (47)$$

A proper selection of “geometric” models is very important for ceramic systems because oxide components can be dissimilar and the deviations from ideality can be very important. For systems with strong interactions, different extrapolation techniques can give quite different results. On the other hand, although the direct extrapolation provides the correct feature of higher order systems, a more accurate modeling of the diagrams could include ternary interaction parameters (L_{ABC}).

Calculation of Equilibrium and Phase Diagram

Once G^φ of the phases of the system are known, minimum energy criteria can be applied to calculate the equilibrium conditions (Eq. 4).

In equilibrium conditions, at constant P and T, the partial Gibbs energies of all phases are identical to the equilibrium chemical potentials, μ_i (Eq. 6):

$$G_i^\varphi(T, P, x_i^\varphi) = \mu_i^\varphi; (i = 1, \dots, c, \varphi = 1, \dots, p) \quad (48)$$

so that, Eq. (48) results in n non-linear equations that can be used in numerical calculation:

$$\begin{aligned} \mu_1^1 &= \mu_1^2 = \dots \mu_1^\varphi \\ \mu_2^1 &= \mu_2^2 = \dots \mu_2^\varphi \\ &\dots\dots\dots \\ \mu_n^1 &= \mu_n^2 = \dots \mu_n^\varphi \end{aligned} \quad (49)$$

The minimum of G can be evaluated numerically by iterative techniques like the Newton–Raphson method (Deiters, 1985). In this approach, one needs an initial constitution for each phase in order to find the minimum of the Gibbs energy surface for the given conditions.

The classical method for obtaining the minimum of the Gibbs energy is the use of Lagrange multipliers μ_i and λ^φ related to the $N_{el} + N^\varphi$ physical constraints (mass balance equation for each of the N_{el} elements, sum of the molar fractions equal to unity in each of the N^φ phases). The Lagrange function, L , is written as:

$$L = \sum_{\varphi=1}^{N^\varphi} n^\varphi G_m^\varphi + \sum_{\varphi=1}^{N^\varphi} \mu_i \left(n_i - \sum_{\varphi=1}^{N^\varphi} n^\varphi x_i^\varphi \right) + \sum_{\varphi=1}^{N^\varphi} \lambda^\varphi \left(1 - \sum_{i=1}^{N_{el}} x_i^\varphi \right) \quad (50)$$

where the molar Gibbs energy of the phase φ is G_m^φ , n^φ is the number of moles of the phase φ and x_i^φ is the molar fraction of the i^{th} element in the phase φ . Then, a non-linear system of $N^\varphi(N_{el} + 1)$ Lagrange-type equations (Eqs. (51) and (52)) must be solved, usually using a Newton-Raphson algorithm, in addition to the $N_{el} + N^\varphi$ initial constraints (53) and (54):

$$\frac{\partial L}{\partial n^\varphi} = G_m^\varphi - \sum_{i=1}^{N_{el}} \mu_i x_i^\varphi = 0 \quad (51)$$

$$\frac{\partial L}{\partial x_i^\varphi} = n^\varphi \left(\frac{\partial G_m^\varphi}{\partial x_i^\varphi} - \mu_i \right) - \lambda^\varphi = 0 \quad (52)$$

$$1 - \sum_{i=1}^{N_{el}} x_i^\varphi = 0 \quad (53)$$

$$n_i - \sum_{\varphi=1}^{N^\varphi} n^\varphi x_i^\varphi = 0 \quad (54)$$

The final results give the values of the initially unknown quantities: the amount n^φ of the various phases, their compositions given by the x_i^φ and the Lagrange multipliers λ^φ and μ_i , these μ_i being considered as the chemical potentials of the i^{th} elements. In summary, all information regarding the thermodynamic equilibrium has been calculated.

Calculation Software Packages

Finding the *real* thermodynamic equilibrium conditions in a system from Gibbs energy minimization is a core issue in calculation software. Nowadays, a variety of database and powerful thermodynamic software packages enable phase diagram calculations of

multicomponent systems. A few of the more well-known commercial ones are: ChemSage (Eriksson and Hack, 1990); Thermo-Calc (Sundman *et al.*, 1985); FacTSage (Bale *et al.*, 2009); MTDATA (Davies *et al.*, 2002); PANDAT (Cao *et al.*, 2009); HSC (See Relevant Websites section) or CaTCalc (Shobu, 2009). There are also general noncommercial sources for thermodynamic calculations like, for example, the classic Lukas program (Lukas *et al.*, 1977; Solgasmix Eriksson, 1975) or more recently, the Open Calphad (Sundman *et al.*, 2015) initiative devoted to develop free software and databases for thermodynamic calculations for different applications.

Some of the first generation software packages such as for example ChemSage, Lukas programs or Thermo-Calc already have the availability of optimizing modules for the calculation of the Gibbs energy functions, which enables users to develop their own database. In spite of the enormous advances made in phase diagram calculations, serious shortcomings of the first generation software became obvious (Chen *et al.*, 2001) due to the fact that the algorithms used in calculating equilibrium conditions were based on local function minimization routines. Chen *et al.* (2001) used a second-generation software package, PANDAT, based on global optimization algorithms to calculate the stable phase diagrams for a given set of thermodynamic parameters. From early 2000, Global Minimization Technique has been implemented in the most generalist software packages.

Subsequently, capacities of the calculation programs have improved at all levels: user interfaces, development of databases, calculation algorithms and special task. The development of increasingly user-friendly computer interfaces makes phase-diagram information more accessible for the occasional user. The user needs only to supply a bulk composition and temperature limits for the calculation, and the programs generate the remaining conditions that are needed for the calculation.

More recently, the challenge of integrating the simulation of kinetic processes with equilibrium calculations has been addressed. Simulation of precipitation, diffusion or phase field simulation of microstructure in metallic systems can actually be performed with, for example, MatCalc, PANDAT, Thermo-calc (DICTRA) or FacTSage software.

The reliability of the results of thermodynamic modeling depends on the quality of the underlying thermodynamic database. Currently, several databases for metals, non-metals, oxides, salts, nitrates, aqueous solutions, etc., have been developed making it impossible to list all of them here so that only a short note about generalist thermodynamic databases widely used in thermodynamic calculations in ceramic systems is presented next. Through the years, there have been a significant interest in defining and collecting thermodynamic data to develop simple and generalist databases such as, for example, those of Dinsdale (1991), Barin and Knacke (1973) or Glusko *et al.* (1982); a short review is given by Jacobson (2001). Since the middle of the 20th century, several international organizations have dedicated efforts to generate comprehensive and self-consistent databases. Some significant examples are SGTE (Scientific Group Thermodata Europe); NIST (United States National Institute of Standards and Technology); NEA (Nuclear Energy Agency); and NPL (National Physical Laboratory, UK) which develop work collecting and normalizing databases for applications in different fields.

The SGTE Pure Substances Database has been widely adopted within the international community as a rigorous basis for the critical assessment of thermodynamic data. In addition to pure substances, thermodynamic data of solution phases have been also considered in the database in terms of non-ideal substitutional and sublattice models.

The JANAF Tables (Joint-Army-Navy-Air-Force) project was established in 1959 to collect thermochemical data for rocket propellant performance calculations by industry and agencies of the Defense Department of USA. Nowadays, the NIST-JANAF thermodynamic table is a computerized database maintained by the United States National Institute of Standards and Technology.

There are some databases comprising thermodynamic properties of multicomponent oxide and non-oxide solution phases which are of great interest in ceramic materials. General databases are focused on specific applications such as those containing Al_2O_3 , CaO , MgO , SiO_2 , $\text{FeO}/\text{Fe}_2\text{O}_3$ and SO_4^{2-} with applications to cements or slags, ZrO_2 or Si-Al-N-O solution phases among others. These databases are a very dynamic field of research and are continuously being revised and updated. Some of the most extensive for oxide solution phases are the FToxid database (Decterov, 2018), (FactSage) for slags, glasses, ceramics or refractories and TCOX, SLAG4 and ION databases (Thermo-Calc) for oxides, slags or cement.

Examples

As examples of application of CALPHAD methodology to ceramic systems, thermodynamic assessments of the binary $\text{CaO-P}_2\text{O}_5$ and ternary $\text{ZrO}_2\text{-CaO-MgO}$ systems are presented.

Thermodynamic Assessment of the Binary $\text{CaO-P}_2\text{O}_5$ System

This system with solid and liquid phases is very interesting because of its application to different biomaterials. Phosphorus is also important in slags and it has been included in other databases in low concentrations.

Serena *et al.* (2011) used the CALPHAD methodology to carry out the thermodynamic assessment of the $\text{CaO-P}_2\text{O}_5$ systems using the Thermo-Calc Software. The system $\text{CaO-P}_2\text{O}_5$ presents several intermediate compounds with different polymorphic forms: P_2O_5 , $\text{CaP}_4\text{O}_{11}$ (CP2); $\text{Ca}_2\text{P}_6\text{O}_{17}$ (C2P3); $\text{Ca}(\text{PO}_3)_2$ (CP); $\text{Ca}_2\text{P}_2\text{O}_7$ (C2P); $\text{Ca}_3(\text{PO}_4)_2$ (C3P); $\text{Ca}_4(\text{PO}_4)_2\text{O}$ (C4P); and CaO . No solid solutions have been reported in the system. The standard Gibbs free energy of P_2O_5 , CaO , CP, $\gamma/\beta/\alpha\text{-C2P}$ and $\beta/\alpha/\alpha'\text{-C3P}$ were taken from the SSUB4 database (SGTE Substance databases). Taking into account bibliographic information, a set of thermodynamic functions were optimized for the $\text{CaP}_4\text{O}_{11}$, $\text{Ca}_2\text{P}_6\text{O}_{17}$, and $\text{Ca}_4(\text{PO}_4)_2\text{O}$ compounds. Very scarce thermodynamic data have been published about thermodynamic properties of CP2 and C2P3 compounds. From structural studies of

phosphate phases it was established that CP2 and C2P3 compounds are constituted by Q^3 and Q^2 tetrahedra so that in this assessment, their Gibbs energies were calculated as binary stoichiometric phases (Eq. 18) from mixtures of P_2O_5 and $Ca(PO_3)_2$ phases:

$$^{\circ}G_{CaP_4O_{11}}^{Solid} - H^{SER} = ^{\circ}G_{Ca(PO_3)_2}^{Solid} + ^{\circ}G_{P_2O_5}^{Solid} + A_{CP2} + B_{CP2}T \quad (55)$$

$$^{\circ}G_{Ca_2P_6O_{17}}^{Solid} - H^{SER} = 2 \cdot ^{\circ}G_{Ca(PO_3)_2}^{Solid} + ^{\circ}G_{P_2O_5}^{Solid} + A_{C2P3} + B_{C2P3}T \quad (56)$$

Standard Gibbs energy of C4P was fitted to various experimental data collected from literature using the general expression from (Eq. 9):

$$^{\circ}G_{Ca_4(PO_4)_2}^{Solid} - H^{SER} = A + BT + CT \ln(T) + DT^2 \quad (57)$$

However, the key to model this glass-forming system is the selection of a suitable thermodynamic model to describe the liquid phase. The authors selected the ionic two-sublattice model (Sundman, 1991) to describe the liquid phase of the CaO- P_2O_5 system. In this model, the liquid phase is described by ionic-two lattices, one of the cations and the other of anions and neutral species following that described in the Section on "Thermodynamic models for ceramic systems". In this way, Serena et al. (2011) described the constitution of the liquid phase based on the structure of phosphate melts and glasses collected in the literature. Structures of typical phosphate melts and glasses have been previously established and they are constituted by a network of $[PO_4]$ tetrahedral (Stocha et al., 2016). These tetrahedra are classified using the Q^n terminology where n represent the number of bridging oxygen per tetrahedron. The phosphate tetrahedral sites that can exist in phosphate glasses are: Q^3 related to P_2O_5 species, Q^2 related to PO_3^{3-} species, Q^1 related to $P_2O_7^{4-}$ species, and finally Q^0 without bridging oxygens corresponding to the PO_4^{3-} species (Fig. 5). The addition of a modifying oxide to P_2O_5 results in the creation of nonbridging oxygens, at the expense of bridging oxygens, so that the speciation of the P_2O_5 occurs and PO_3^- ; monophosphate (PO_4^{3-}) and diphosphate ($P_2O_7^{4-}$) species appear in the glass structure.

Considering the previous, the liquid phase of the system, was defined by the formula $(Ca^{2+})_P:(O^{2-}, PO_3^-, PO_{7/2}^{2-}, PO_4^{3-}, PO_{5/2}^-)_{Q^i}$ where P and Q change with composition to maintain electroneutrality as described by the equations:

$$P = \sum_i \gamma_i (-\gamma_i) = 2\gamma_{O^{2-}} + \gamma_{PO_3^-} + 2\gamma_{PO_{7/2}^{2-}} + 3\gamma_{PO_4^{3-}} + 0\gamma_{PO_{5/2}^-} \quad (58)$$

$$Q = \sum_j \gamma_j (\gamma_j) = 2\gamma_{Ca^{2+}} = 2 \cdot 1 = 2$$

where γ_i and γ_j are the site fraction, i.e., the fraction of the species i and j in a particular sublattice, and γ_i the corresponding electrical charge.

Considering the general expression for the Gibbs energy of the ionic two-sublattice model, (Eqs. 38–41; the Gibbs energy of the liquid phase in the system CaO- P_2O_5 , is given by the equation:

$$G_m^{Liquid} = \gamma_{Ca^{2+}} \gamma_{O^{2-}} ^{\circ}G_{Ca^{2+}:O^{2-}}^{Liquid} + \gamma_{Ca^{2+}} \gamma_{PO_3^-} ^{\circ}G_{Ca^{2+}:PO_3^-}^{Liquid} + \gamma_{Ca^{2+}} \gamma_{PO_{7/2}^{2-}} ^{\circ}G_{Ca^{2+}:PO_{7/2}^{2-}}^{Liquid} + \gamma_{Ca^{2+}} \gamma_{PO_4^{3-}} ^{\circ}G_{Ca^{2+}:PO_4^{3-}}^{Liquid} + 2\gamma_{PO_{5/2}^-} ^{\circ}G_{PO_{5/2}^-}^{Liquid} \\ + P \cdot RT \left(\gamma_{O^{2-}} \ln(\gamma_{O^{2-}}) + \gamma_{PO_3^-} \ln(\gamma_{PO_3^-}) + \gamma_{PO_{7/2}^{2-}} \ln(\gamma_{PO_{7/2}^{2-}}) + \gamma_{PO_4^{3-}} \ln(\gamma_{PO_4^{3-}}) + \gamma_{PO_{5/2}^-} \ln(\gamma_{PO_{5/2}^-}) \right) \\ + Q \cdot RT (\gamma_{Ca^{2+}} \ln(\gamma_{Ca^{2+}})) + {}^{xs}G^{Liquid} \quad (59)$$

Fig. 5 Schematic representation of PO_4 tetrahedral units in phosphate glass structure, described using the Q^n designation. (a) Q^3 three Bridging oxygens, (b) Q^2 two Bridging oxygens, (c) Q^1 one Bridging oxygen and (d) Q^0 no Bridging oxygens.

where ${}^{\circ}G_{Ca^{2+},O^{2-}}^{Liquid}$ is equal to the standard Gibbs energy of two moles of pure liquid CaO, and ${}^{\circ}G_{PO_5/2}^{Liquid}$ the corresponding value for $\frac{1}{2}$ mol of pure liquid P_2O_5 . On the other hand, ${}^{\circ}G_{Ca^{2+},PO_3^-}^{Liquid}$, ${}^{\circ}G_{Ca^{2+},PO_2^-}^{Liquid}$ and ${}^{\circ}G_{Ca^{2+},PO_4^{3-}}^{Liquid}$ can be related to standard Gibbs energy of pure solid with stoichiometry $Ca(PO_3)_2$, $Ca_2P_2O_7$, and $Ca_3(PO_4)_2$, respectively.

The excess Gibbs energy depends upon the interactions between species within the same sublattice, in this case, the anionic sublattice, which is given by the equation:

$${}^{xs}G^{Liquid} = \sum_{i \neq k} \gamma_i \gamma_k \left[(\gamma_i - \gamma_k)^n \cdot {}^nL_{Ca^{2+};i,k}^{Liquid} \right] \quad (60)$$

where i and k are the species in the anionic sublattice and ${}^nL_{Ca^{2+};i,k}^{Liquid}$ is the interaction parameter between the species i and k in the presence of the ion Ca^{2+} .

Afterwards, the optimization of the introduced parameters was made using the module PARROT (parameters optimization module) in Thermo-Calc Software. As a result of the optimization, one set of model parameters for the Gibbs energies of the compounds CaP_4O_{11} , $Ca_2P_6O_{17}$, and $Ca_4(PO_4)_2O$ and the liquid phase were assessed.

Phase equilibrium diagram of the system CaO - P_2O_5 resulting from the assessment, compared to experimental data is presented in Fig. 6. The calculation predicts that CP2, CP, C2P, and C3P compounds melt congruently while the C2P3 and C4P compounds melt incongruently. C4P evidences a peritectic relationship with CaO, and an eutectic point with α' -C3P.

An acceptable agreement between the thermodynamic calculation and the experimental invariant points can be observed in the P_2O_5 -rich region of the system. The liquidus surface as well as the invariant points in the region between 0.3 up to 0.75 mol fraction of CaO were very well reproduced by these calculations.

Besides, site distributions calculated for the liquid could be compared with the experimental tetrahedral distributions of Q^n in calcium-phosphate glasses. To illustrate this, species distribution in the metastable liquid phase at 300°C and liquid phase at 1500°C were also calculated (Fig. 7). The distribution of species in the melt at different temperatures are in line with the proportions of Q^i tetrahedra observed in the corresponding glasses collected from the literature. At 300°C , the distribution of species calculated matched the ideal relations. However, at higher temperatures, the proportion of species deviated from the ideal behavior and the mixture of species increased in all the compositions. The ability of liquids to accommodate different structural configurations as a function of temperature distinguished them from solids, and the increased disorder with temperature in the distribution of species has been experimentally observed in melts and glasses, so that the proposed model is very realistic.

Thermodynamic Assessment of the ZrO_2 -CaO-MgO Ternary System

Zirconia can be found in three crystalline forms: monoclinic, tetragonal and cubic, depending on temperature and presence of doping elements. This offers the possibility of designing high-performance materials with advanced properties by controlling the phase relations and microstructure of the material. Ceramic materials based on cubic- ZrO_2 present high refractoriness, chemical

Fig. 6 Calculated phase equilibrium diagram of the P_2O_5 -CaO system, after [Serena et al. \(2011\)](#). (a) Overall view, (b) 0.3–0.55 mol fraction CaO and (c) 0.66–0.82 mol fraction CaO. Experimental data provided by various authors are represented in the figure.

Fig. 7 Calculated species distribution in the liquid phase of the system P_2O_5 -CaO, after *Serena et al. (2011)*. (a) Metastable liquid at 300°C and (b) Stable liquid at 1500°C. Experimental data provided by various authors.

inertness and corrosion resistance at high temperatures and those with tetragonal- ZrO_2 show excellent mechanical properties. Some outstanding applications of these materials are: (1) c - ZrO_2 as oxygen sensors, thermocouple protection tubes, furnace muffles, liners, crucibles, high temperature heating element supports, (2) ceramics based on ZrO_2 -CaO system are used as high-temperature electrolytes in fuel cells, piezoelectric oscillator transducers, heat-resistant linings in furnaces, and protective coatings on alloys, and more recently, (3) MgO-stabilized zirconia as a biomaterial with biomechanical compatibility for zirconia-based osteoimplants.

Because of their high interest, several thermodynamic assessments of ZrO_2 -based systems have been published and some of them have been included in commercial databases. As an example, thermodynamic assessment for the system ZrO_2 -CaO-MgO from its binary sub-systems developed by *Serena et al. (2005)* is summarized below.

In this assessment, the binary systems MgO-CaO, ZrO_2 -CaO and ZrO_2 -MgO were evaluated and then extrapolated to the ternary system using the symmetric model proposed by *Muggianu et al. (1975)*. These calculations were carried out using Thermo-Calc Software.

The stable solid forms of the end-components of the system are: CaO (cubic), MgO (cubic) and ZrO_2 which presents three polymorphic forms depending on temperature: monoclinic (m- ZrO_2) $T < 1170^\circ C$; tetragonal (t- ZrO_2) ($1170^\circ C < T < 2370^\circ C$) and cubic (c- ZrO_2) ($T > 2370^\circ C$).

Beside liquid phase, different solution phases were considered: CaO and MgO adopt solid solution with MgO and CaO respectively and both have fcc cubic structure so that they were modeled as one unique phase named Halite, and t- ZrO_2 and c- ZrO_2 polymorphs with solid solutions of both CaO and MgO (Tss and Css). No ordering effects were reported in the liquid nor in the solid solution phases so that a random substitutional model was selected. Therefore, Gibbs energy of the binary solution phases ϕ were calculated using a subregular solution model (see *Eqs. 19–21*):

$$G_m^{\phi-bin} = \sum_i x_i \cdot {}^0G_i^{\phi} + RT \sum_i x_i \cdot \ln(x_i) + {}^{xs}G_{ij}^{\phi-bin} \quad (61)$$

$${}^{xs}G_{ij}^{\phi-bin} = x_i x_j ({}^0L_{ij} + (x_i - x_j) {}^1L_{ij})$$

$i, j = MgO, CaO, ZrO_2; \phi = Liquid, Halite, Tss, Css$ (62)

In this assessment, m- ZrO_2 was considered as pure phase and two stable stoichiometric compounds $CaZrO_3$ and $Ca_6Zr_{19}O_{44}$ (named F2 phase) were considered in the binary system ZrO_2 -CaO. ${}^0G_i^{\phi}(T)$ of these phases was expressed according to *Eq. (6)*.

Lattice stabilities for the stable forms were taken from SSUB4 database while data for metastable forms and binary intermediate compounds were those reported by *Yin and Argent (1993)*. Binary interaction parameters ${}^0L_{ij}$ and ${}^1L_{ij}$ were optimized for each binary phase.

Once the agreement with the experimental data of the binary systems was verified, Gibbs energy of ternary solution phases was extrapolated from binaries. A ternary parameter for the Css phase was necessary to properly fit the liquidus and solid solution experimental data.

The liquidus surface, calculated for the ternary system (*Fig. 8*); presents three eutectic invariant points:

and

Fig. 8 Calculated liquid surface of the ZrO_2 - MgO - CaO system, modified to include quantitative information about the invariant points of the system. After [Serena et al. \(2005\)](#).

Fig. 9 Calculated isothermal section at 1400°C of the system ZrO_2 - MgO - CaO . After [Serena et al. \(2005\)](#).

Liquid $\rightarrow$ Halite - MgO + Halite - CaO + CaZrO_3 at 1982°C .

Only experimental data for the first eutectic point were reported in the literature by [de Aza et al. \(1974\)](#).

The calculated isothermal section at 1400°C is shown in [Fig. 9](#). Phase compatibility of CaZrO_3 and MgO -rich Halite phase is evidenced. Due to the significant solid solutions of MgO and CaO in the ZrO_2 structures, wide stability fields of C_{ss} and $\text{C}_{ss} + \text{T}_{ss}$ can be observed. Once the thermodynamic assessment is performed, any isothermal section of the system could be calculated which provides a basic tool to design ZrO_2 -based ceramics.

Finally, the calculated isoplethal section $\text{MgO} \cdot \text{CaO} \cdot \text{ZrO}_2$ (dolomite-zirconia) is presented in [Fig. 10](#) which shows phase compatibilities through the line $\text{MgO}/\text{CaO} = 1$ to ZrO_2 . Knowledge of this section is basic to designing ceramic materials from a natural raw material such as Dolomite ($\text{MgCa}(\text{CO}_3)_2$) with a molar ratio of $\text{MgO}/\text{CaO} = 1$. The primary crystallization fields of ZrO_2 , CaZrO_3 , MgO and CaO appear in the section. The three eutectic invariant points of the system as well as eutectoid invariant

Fig. 10 Calculated isoplethal section $\text{CaO} \cdot \text{MgO}-\text{ZrO}_2$ of the system $\text{ZrO}_2\text{-MgO-CaO}$. After *Serena et al. (2005)*.

point associated with the ZrO_2 polymorphic transformations are projected in/on the isoplethal section. The stability field of the F2 phase is included in the section too.

Phase compatibilities of CaZrO_3 as a function of temperature are very important to design the composition and thermal treatment of MgO-CaZrO_3 based materials for refractories applications while studies in the ZrO_2 -rich region provide evidence for the compatibility, solid solution limits and transformation temperatures of the different polymorphs of ZrO_2 phases which are fundamental to design of zirconia based materials.

Characterization of Ceramic Powders

Martin J Murtagh, Cornell University, Ithaca, NY, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

Historically, methods that represent particle-level (static) characterizations have been deemed necessary to qualify component raw materials and batch in the processing of various oxides, carbides, nitrides and other materials used in ceramic and glass batching (Reed, 1995; Schubert and Petzow, 1990; Balasubramanian *et al.*, 2012). While these represent well-established protocols, these measures are necessary but often insufficient to adequately describe specific particle-level attributes that influence the bulk processing of a given component or batch (Tomas, 2001a).

Inattention to flow regimes (e.g., transformative attributes such as frictional slow flow (quasi-static) elastic-inertial (intermediate), and inertial-collisions (fluidization) as well as compressibility, permeability, internal angles of friction, etc.) favors a predisposition towards classic static characterization techniques obscuring valuable information necessary to understanding de-mixing of complex inorganic granular and powder bed systems (Mort *et al.*, 2015; Tomas, 2001b). Conventional approaches in materials processing establish three commonplace topics: as formed structure, properties and performance. It is our intent to show that an understated and insufficiently addressed portion of processing of materials is the quasi-static, intermediate and fluidized flow regimes during bulk processing of batch (multicomponent) systems.

Current Static Measures

Materials science and technology is based on control of the triaxial space of structure, properties and processing. To achieve the desired properties and structure of a final product, various comminuted raw materials are blended with the interest of meeting a target chemical composition to be processed to meet the final product's specifications.

To assess the suitability of comminuted materials to meet the target attributes of organic and inorganic processing, classic static raw material characterization protocols have required one or more of the following seven types of measurement:

- (1) Chemical composition.
- (2) Mineral and crystallite makeup.
- (3) Particle shape and size distribution.
- (4) Pore shape and size distribution.
- (5) Specific surface area.
- (6) Bulk and/or skeletal density.
- (7) Microscopy and imaging methods.

Common chemical analysis techniques available for static measure of powders are typically spectroscopic methods. These include inductively coupled plasma (ICP) flame emission/mass spectrometry, X-ray fluorescence (either via standalone methods or in tandem with electron microscopy such as electron dispersive spectroscopy or EDS and wavelength dispersive spectroscopy or WDS). Additional spectroscopic methods available include dissolution and digestion of powder species for spectrophotometry or ion chromatography for chemical speciation. Additional solution methods include Fourier transformed infrared spectroscopy (FTIR). The aforementioned techniques should be noted as being bulk characterization methods for powder elemental analysis. When expanded to predominantly surface characterization techniques, additional methods such as Raman spectroscopy, secondary ion mass spectrometry (SIMS), X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES) and Rutherford backscattering spectroscopy (RBS) should also be noted for surface chemistry measurement (King, 2002).

Mineral and crystallite makeup for powders is most commonly characterized via X-ray diffraction and associated quantitative analysis techniques such as Rietveld refinement. Alternate mineralogical analysis is performed via birefringence of polarized light in optical microscopy (King, 2002; Bloss, 1961).

Historically particle sizing has been conducted through the use of sieves of varying apertures to construct a distribution of the mass of material retained on a screen of known mesh aperture size. Due to these origins in screening, particle size conventions originated with the so-called cumulative percent coarser than distribution or CPCT (which, when reversed, creates the so-called cumulative percent finer than distribution or CPFT). The use of sieves is commonplace in modern sizing based on low equipment cost, sampling considerations, measurement size range and resolution of the desired distribution. It should be noted that sieves are not commonly used for characterizing particles below 45 μm or 325 mesh. Based on tendencies to emphasize utility of histograms for representation of data, the differential between sieve retention populations can be used to generate the so-called incremental of differential size distributions. When evaluated over infinitesimal differentials in particle diameter, the convenience of incremental distributions is the ability to fit to mathematical functions for describing particle size distribution (Allen, 2003).

Alternate classical sizing principles such as gravitational (or centrifugal) sedimentation have been incorporated into techniques such as X-ray sedigraphs, which measure the attenuation of a turbid suspension over time to quantify particle size distribution. In

the modern era, the Coulter principle is used to characterize particle size through obscuration of an electrical sensing zone. Particle counting is typically performed via obscuration of photodiode detectors or via microscopy methods. Among the most prevalent methods used today are static and dynamic light scattering, which utilize Mie scatter/Fraunhofer diffraction and photon correlation spectroscopy respectively to quantify particle size distribution. All of the aforementioned techniques can be represented via cumulative and/or incremental distributions (Allen, 2003).

Alternate techniques utilized today include the Sauter mean diameter, which manipulates the particle skeletal density and the powder specific surface area to calculate the equivalent spherical diameter. Through manipulation of pycnometric and surface area data, this method is typically used to characterize primary particles in highly agglomerated systems where techniques such as static light scattering may misleadingly characterize the agglomerate size as the particle size. Alternate methods used primarily for characterization of agglomerated nanosized particles can include differential mobility analysis, which uses the electrical mobility of particles to determine their size (Eggersdorfer *et al.*, 2012).

One additional technique to consider is the so-called undertone method whereby colorimetry is used as a proxy for particle size measurement. In titanium dioxide for example, the addition of carbon black changes the proportions of red and blue light absorbed by the powder and thereby causes varying colors based on particle size, where coarser particles upon addition of carbon black would scatter more red light wavelengths and finer particles would scatter more blue light wavelengths (Völz *et al.*, 2000).

Pore shape and size distribution of powders can be achieved through various techniques. Mercury porosimetry utilizes the controlled wetting and intrusion of mercury into particles to measure the volumetric size distribution of voids. Physisorption methods such as *t*-plots or capillary condensation utilize the controlled adsorption of nitrogen, argon, or carbon dioxide to measure the pore size distribution. Additional methods that have been employed or explored include cryo- and/or T2 shift NMR and thermoporometry via measurement of melting/freezing point shifts in differential scanning calorimetry. Alternate techniques for porosity measurement include X-ray tomography and image analysis (Allen, 1997; Diamond, 1971; Sing *et al.*, 1985; Alnaimi *et al.*, 1994; Wulff, 2004).

Powder specific surface area is often measured via gas physisorption methods whereby a quantity of powder material is cooled to cryogenic temperatures and the volume of gas adsorbing onto the powder surface below saturation vapor pressures is measured. Additional techniques that have been historically employed to measure specific surface area include the addition of dyes such as methylene blue and measuring the quantity of dye required to fully coat the powder surface. This has been particularly of use in the clay industry (Allen, 1997; Brunauer *et al.*, 1938; Sing *et al.*, 1985; Kipling and Wilson, 1960).

Classical methods for bulk or skeletal density measurement are pycnometric in nature (i.e., requiring the measurement of the powder volume in a vessel previously characterized for its empty volume, thereby rendering the difference in fill volume after addition of the powder species as a measure of bulk and/or skeletal density). The filling medium to facilitate this difference measurement varied depending on the target analyte (powder bulk density or skeletal density) (Allen, 2003).

Skeletal or “true” density of a powder has been measured by a Gay-Lussac pycnometer where a liquid of well-characterized density was added to a pre-measured mass of powder in a vessel of calibrated volume. The evolution of the Gay-Lussac pycnometer is modern-day helium pycnometry whereupon helium gas is used in place of an infiltrant and the dosing and measurement procedure is typically automated and computerized. Similarly, mercury porosimetry can be manipulated to perform pycnometric measurements according to the same principle of measuring the differential between an empty and vessel volume and the intruded volume of a powder species. An alternate non-pycnometric method for measurement of skeletal density would be the aforementioned Rietveld refinement via X-ray diffraction to determine atom positioning and calculation of the “true” density based on the identified unit cell (Allen, 2003).

Bulk density measurements are similarly performed using pycnometric principles. The most prevalent technique is gravitational pycnometry or “tap density” whereupon a quantity of powder is filled to a measured height in a graduated cylinder and the cylinder is tapped by a controlled number of repetitions. The number of taps and the graduated cylinder volume is established for various materials and varies according to written ASTM methods (Allen, 2003; Völz *et al.*, 2000).

For measurement of interparticle void volume and the envelope volume of particles with high pore volume and/or highly fractal surface texture, horizontal pycnometry uses the infiltration of incompressible solid media to occupy the interstitial volume of a powder bed in a pre-calibrated chamber volume. Upon knowing the volume of media added in comparison with the vessel free available volume, the envelope volume and/or density of the particles can be measured (Allen, 2003).

The use of microscopy and imaging for characterizing particles can be to infer qualitative characteristics of powders and particles or to directly measure particle attributes such as size distribution and/or shape. Historical characterization via imaging techniques, whether by optical or electron microscopy have been restricted to capturing two-dimensional characteristics of particles, with three-dimensional information obtained via techniques such as stereoscopic imaging. Recent advances have expanded visualization to the use of three dimensional methods such as scanning laser confocal microscopy or tomographic methods via focused ion beam, X-ray or electrical capacitance. For quantitative metrics, imaging is often utilized to calibrate measurement data from alternate techniques where the assumptions of equiaxed shape are believed to skew measurement data and interpretation based on the limitations of physical principles involved in measurement. A common example cited is the measurement of highly anisotropic particles where light scattering data interpretation becomes ambiguous with respect to the axis of orientation. Methods to circumvent this limitation via imaging involve the use of common size measurements based on an arbitrary axis of rotation. Examples of these include the Feret diameter and the Equivalent Spherical Diameter (or equivalent circular diameter) which measures the three-dimensional volume (or two-dimensional area, depending on the method of imaging) and then identifies the diameter of a sphere required to have an equivalent volume (or circle required to have an equivalent two-dimensional area). These various metrics and others utilizing similar computational and numerical principles are accessed through common third-party image analysis software packages when not directly acquired through instrument analysis packages. Examples of commercially available third party packages for image analysis

can include Adobe Photoshop®, ImageJ, MatLab® and Python-based platforms via SciPy image processing kits such as Anaconda® (Maire *et al.*, 2011; Zhu *et al.*, 2003; Tang *et al.*, 2008; Cierpka and Kähler, 2012).

It should be noted that for characterization of size distribution via imaging, the pathway to quantification includes identifying individual particles and is therefore reflective of a number-based size distribution. By contrast, sieving, light scattering and sedigraph methods are reflective of particle volumetric distributions and/or mass. The distinction is crucial and necessary due to common practices of correlating imaging data to alternate techniques of sizing including the aforementioned light scattering and sieve data (Pieri *et al.*, 2006).

Quantification of shape is most commonly thought of as measurement of particle aspect ratio, defined typically as the major (or longer) axis of the particle divided by the minor (or shorter) axis; the reciprocal of this value are also used to confine the values between 0 and 1. Alternate shape characterization metrics include particle perimeter, area, orientation, rectangularity, roundness and texture. As with size measurement, these various shape metrics can be accessed by image analysis techniques. Common instrumentation operating on principles of micro-fluid imaging passes suspensions of particles through a measurement flow cell where the imaging and quantification of these particle properties is done on-line in real-time via optical techniques (Mikli *et al.*, 2001; Cierpka and Kähler, 2012).

Granular and Powder Batch flowability

Granular (size distribution $>100\ \mu\text{m}$) and powder (size distribution $<100\ \mu\text{m}$) bed flowability are not described via classical descriptors as for fluids & gases due to inadequate understanding of the bulk state of granular and powder materials from the particle level (Zhua *et al.*, 2007; Bell, 2005). Restricting granular and powder bed characterization to the seven aforementioned techniques ignores complexities and interactive effects of multi-component batches in transport.

First principle models exist for effects such as particle-level (static) flowability and friction, adsorption kinetics, hygroscopicity, etc. (Zhua *et al.*, 2007; Kamrin, 2008). Academic and industrial scientists are not ignorant of the quasi-static, intermediate and fluidized regimes impact on transformative transport properties. However, these are essentially handled in “brute force” techniques such as spray drying to wholly transform powder flow properties where economically viable. Quantification of flowability of the bulk solid mass has historically been limited to the widely-criticized angle of repose measurement, which itself is not one of the aforementioned “stock” protocols. Literature on spray drying in the bulk processing of inorganics has been more strongly focused on optimizing the parameters to facilitate this “brute force” technique than to correlate its improvements to spray drying process parameters (Lukasiewicz, 1989).

This is not to suggest that spray drying is exclusively motivated by concerns of powder flow (and in the absence of knowledge and/or tests a “brute force” mass spray drying is employed); many other advantages and motives exist for spray drying beyond achieving high flowability but this is an example of the awareness of concerns regarding flow without a rigorous method to measure it.

The lack of full understanding of bulk powder flow from the particle level as a continuum, forces empirical modeling of bulk systems with the inability to sufficiently define continuum and successfully bridge powder to particle-level mechanics and modeling (Tomas, 2004).

The following are examples of complementary tests at the granular and powder scale obtained through the authors’ experimentation measuring bulk behavior (albeit empirically). It is the authors contention that these complementary tests provide more insight into the processing of complex single or multicomponent (batch) systems than spurious correlations drawn from the exclusive use of static measures.

(1) Example of powder flow consideration in an industrial holding bin

An example is shown in Fig. 1 of a multi-component powder batch system, its constituent particle size distributions, their mathematical reconstitution per nominal formulation and a measurement of particle size of the actual mixed batch.

Fig. 1 Composite particle size distribution including batch subcomponents and mathematical reconstitution per batch formula.

Fig. 1 and **Table 1** show how the individual components of a batch can be mathematically proportioned to create a composite master batch to meet a target stoichiometry in the bulk. However, merely addressing the stoichiometry from a bulk perspective denies potential consequences of inhomogeneous transport (quasi-static flow, i.e., slow frictional flow) during a process event such as discharging a mixed batch from a silo. As shown in **Fig. 2**, an experiment was conducted where a holding bin (comprised of an axi-symmetrical cylinder and a conical outlet section) was dispensed from 85% fill in the cylindrical section to a level above entry into the cone (represented by “X”, with the level prior to entry into the cone re-scaled to 100%) was utilized to facilitate mass flow of the batch; a second experiment was conducted where the refilling and dispensing of the bin to a height below this level was intended to facilitate funnel flow, as shown on the right hand side of **Fig. 2**.

Attempting to dispense the holding bin in a mass flow regime results in a relatively unchanged particle size distribution as measured by the weight percent retained on screens for fine material ($< 106 \mu\text{m}$) and coarse material ($> 600 \mu\text{m}$). However, note that when bin refill practices allow dispensing material to levels below the fill height of the cone (i.e., less than 100% of the fill level of the cone), transient effects of particle size distribution variation due to bin fill are evident, as measured by the increased variation of the aforementioned sieve weight percent retained on a coarse screen and the fine fraction collected in the pan. These values of coarse and fine are represented in **Table 1** by the weight percent retained on the $600 \mu\text{m}$ opening (30 mesh) and the cumulative fraction finer than $106 \mu\text{m}$ (represented by the cumulative sum of the “Pan”, 325 mesh and 200 mesh retentions shown in **Table 1**).

The aforementioned data shows how in the bulk we can meet target properties of particle size distribution of a batch and meet target composition of reconstituted batch with measurements in a very bulk scale. However, the time series data for sieve analysis above shows how inattention to transport effects, such as dispensing a holding bin into conditions that foster funnel flow leads to segregation by particle size, thereby causing localized variation of particle size distribution. By definition, segregation in a single component system is by particle size only; for multicomponent systems where discrete batch component particle sizes are present and where local uniformity of components is necessary, inattention to transport properties creates unwanted variation in mix- edness (by phase) at whatever the critical length scale of the process is. As seen in **Fig. 1**, while particle size distribution is not a

Table 1 Composite particle size distribution including batch subcomponents (C1-C5) and mathematical reconstitution per batch formula by weight percent

Sieve opening (μm)	Tyler mesh	C1 (%)	C2 (%)	C3 (%)	C4 (%)	C5 (%)	Mathematical reconstitution (%)	Measured batch (%)
2000	10	0.00	0.01	0.00	0.00	1.03	1.04	3.93
600	30	0.00	1.15	0.00	2.10	15.7	19.1	21.1
300	50	0.03	6.87	0.00	5.78	21.0	34.8	33.2

125	120	0.08	11.9	0.40	8.25	24.1	46.3	42.7
106	140	0.12	12.1	1.85	8.46	24.5	48.6	45.3
75	200	2.63	12.3	6.57	8.63	24.8	56.6	53.4
45	325	28.0	12.4	10.5	8.78	25.0	86.3	84.3
< 45	Pan	40.6	12.4	11.3	8.97	25.0	99.9	99.7

Fig. 2 Batch weight percent for fine and coarse components relative to discharge refill level; 100% bin weight normalized refers to a fill level above entry into the cone.

material property in the classic sense, strong variations of particle size distribution within a batch such as the one shown make it effectively a pseudo-material property confined to this system. Temporal variation in particle size can therefore be seen as a potential temporal variation in material chemical composition due the invariant transport properties.

(1) Batch flowability and aeration at a research-scale

The particle size distributions shown in Fig. 3 were obtained via a common static light scattering method of particle size measurement and show little or no differentiation between a set of four powder batches.

Fig. 4 shows laboratory research-scale ribbon extrusions of these powder batches.

Clearly, particle size distribution alone is insufficient to describe the suitability of the powder batch to form a cohesive contiguous ribbon, as shown by the inferior quality of the extrudate shown in the pictures of 3 and especially 4. Additional characterization of the powder batches was performed by a Freeman Technologies' FT4 powder spindle rheometer (intermediate flow: inertial-elastic) coupled with vessel aeration to monitor the energy of fluidization (fluidized flow: inertial-collisions). Fig. 5(a) and (b) is a plot of the aeration specific flow energy as a function of the aeration flow rate. Fig. 5(a) shows the full range of the data collected while Fig. 5(b) isolates the regime from 0 to 20 mm s⁻¹.

Fig. 3 Particle size distributions for four powder batches.

Fig. 4 Ribbon extrusions of the four batches (labeled “1”, “2”, “3” & “4”), whose particle size distributions were shown previously in Fig. 3.

Fig. 5 (a) Aeration specific flow energy as a function of the aeration flow rate as measured via a Freeman Technologies FT4 powder spindle rheometer. (b) Aeration specific flow energy as a function of the aeration flow rate as measured via a Freeman Technologies FT4 powder spindle rheometer.

Sample 1 shows a continuous steady-state specific energy over the available range of aeration flow rates. Sample 2 similarly shows this continuous profile at a lower steady state specific flow energy, which correlates with the superior quality of extrudate compared with Sample 1, as seen in the pictures above. Sample 3 showed a truncated specific energy steady state due to overloading encountered at 75 mm s^{-1} due to the presence of stubborn agglomerates. Sample 4 exhibited stronger agglomerates and a greater steady-state specific flow energy than Sample 3, causing its specific flow energy measurements to be truncated at a lower aeration flow rate.

Sample 4 was a highly fibrillated “ball”. The greater ease of dispersion and lower effective energy for a given aeration flow rate correlates with the better quality of the extrudate produced (hence the better quality of the ribbon produced in “2”).

(2) Dynamic vapor sorption of phosphate materials and impact of humidity on flowability

Two phosphate raw materials’ (with different cations) particle size distributions are shown in [Fig. 6](#):

Both of the presented phosphate materials show similar particle size distribution ranges falling within the broad classification of granulates. Their susceptibility to moisture sorption can be compared via dynamic vapor sorption (DVS) measurements, as in [Fig. 7\(a\)](#) and [\(b\)](#) while [Fig. 7\(c\)](#) is a plot of relative mass changes at 70% and 90% relative humidity compared with the 0% humidity starting mass. [Fig. 7\(a\)](#) indicates that the relative mass change at 90% relative humidity for phosphate material 1 of 0.3%. By contrast, [Fig. 7\(b\)](#) shows that phosphate material 2 exhibits a relative mass change of 84% of the initial mass, despite the relative similarity in particle size distribution to phosphate material 1. These differences are graphically shown in [Fig. 7\(c\)](#), particularly to highlight the further divergence of the two materials’ behavior between 0% and 90% relative humidity (including the rapid increase observed for phosphate material 2 between 70% and 90% relative humidity).

Fig. 6 Cumulative particle size distributions of two phosphate raw materials by static light scattering.

Fig. 7 (a) Moisture sorption/desorption isotherms at 22°C as a function of relative humidity for Phosphate material 1 (note the relative y-axis scaling) as measured by Dynamic Vapor Sorption. (b) Moisture sorption/desorption isotherms at 22°C as a function of relative humidity for Phosphate material 2 (note the relative y-axis scaling) as measured by Dynamic Vapor Sorption. (c) Mass percent change at select relative humidity values (22°C) for the two phosphate raw materials as measured by Dynamic Vapor Sorption (inset is rescaled to show relative comparisons for Phosphate material 1).

Fig. 7 Continue.

Fig. 8 Relative differences in specific surface area between samples A & B as measured by Brunauer-Emmett-Teller (BET) gas physisorption methods.

The DVS data for phosphate material 2 shows both an irreversible phase change on the desorption step compared with material 1 and two orders of magnitude shift in mass change on exposure to ambient moisture, indicating a spontaneous irreversible reaction at ambient environmental conditions. This irreversible mass change indicates the presence of deliquescence despite similarities in particle size distribution and batching by target mole percent phosphate. The consequence of this effect is an excess of moisture that forces compositional adjustments due to changes in batch stoichiometry by the use of this alternate phosphate source. Moreover, the deliquescence observed for phosphate material 2 indicates further requirements for storage in industrial manufacturing, specifically the requirement for storage below 70% relative humidity as indicated in Fig. 7(c).

Powder Batch Permeability & Compressibility

Figs. 8 and 9 show powder specific surface area (relative) and particle size (hydro-dispersed static light diffraction) for two candidate raw materials, identified as A & B. Fig. 10 is a plot of the bulk density and compressibility of the two materials. Compressibility data was obtained using a Freeman FT4 powder rheometer. Bulk density vs. applied normal stress was captured simultaneously, also via the FT4 rheometer. Fig. 10 that despite common observations of compaction in response to the normal stress, re-scaling indicates that Material B shows a 40% compressibility relative to the 20% compressibility of Material A.

Fig. 11 is a Weibull plot of the data shown in Fig. 10 (bulk density vs. the applied normal stress). The Weibull scaling parameter, or alpha, is the characteristic stress or the stress value required to reach 63.2% of the final bulk density increase. The

Fig. 9 Particle size distribution for samples A & B as measured via a common static light scattering technique.

Fig. 10 Bulk density (g mL⁻¹) and percent compressibility as a function of applied normal stress (kPa) for samples A & B.

Weibull modulus, (β), is the slope of the Weibull plot and represents the narrowness of the compaction rate distribution, i.e., the greater β value the narrower compaction rate distribution. **Fig. 11** indicates that both materials compressibility data fit a Weibull distribution with a correlation coefficient above 0.990 and that Material B shows lower α and β fit parameters than Material A.

The differences observed in particle size (**Fig. 8**) and surface area (**Fig. 9**) are minor when compared to the large differences observed in the compressibility, which impacts the bulk density during a forming process or in the final product attributes. Moreover, in spite of the higher compressibility of material A, note that material B exhibits a greater rate of densification than material A as evidenced by the larger β value in the Weibull plot of **Fig. 11**.

Another example is shown in **Fig. 12** for the evaluation of two lots of the aforementioned raw material "B" via aerodynamic/dry dispersion in static light scattering along with a corresponding generic measurement of the material via hydrodynamic dispersion via the same static light scattering system. The conventional 10th, 50th and 90th percentile diameters are given in **Table 2**.

The "good" and "bad" lots were observed to exhibit differences in manufacturing with respect to bin discharge, assisted with pneumatic conveyance. The so-called "bad" lot was observed to exhibit the common rat holing defect (last in, first out), whereby the effective storage capacity of the bin for refill and discharge was constricted.

Aerodynamic dispersion for static light scattering was used to provide an in-process particle size profile of the two powder lots. Note again that particle size is insufficient to differentiate between the two powder lots.

Fig. 11 Weibull plot of bulk density (g mL^{-1}) as a function of applied normal stress (kPa).

Fig. 12 Comparing so-called “good” and “bad” lots via aerodynamic dispersion at low and high aperture settings to vary aerodynamic dispersion power in comparison with conventional hydrodynamic dispersion and suspension media-based results for static light scattering particle size distribution measurement (a.u. refers to “arbitrary units”).

Table 2 Tabulation of 10th, 50th & 90th particle diameter percentiles for so-called “good” and “bad” lots at low and high aperture settings in comparison with conventional hydrodynamic dispersion and suspension media-based results for static light scattering particle size distribution

Measurement	d_{10} (μm)	d_{50} (μm)	d_{90} (μm)
Good lot - aerodynamic dispersion low aperture	0.734	850.3	1077.0
Good lot - aerodynamic dispersion high aperture	0.694	325.2	465.8
Bad lot - aerodynamic dispersion low aperture	223.0	828.4	1013.0
Bad lot - aerodynamic dispersion high aperture	99.76	793.3	1174.0
Representative aliquot - hydrodynamic dispersion	0.172	0.367	0.687

To address the issue of flowability during discharge, a Jenike & Johansen fluidized segregator was utilized to circulate material and determine the quantity collected at stages positioned at various heights in the aeration column (bottom, middle, top, funnel and filter paper atop the funnel). A photograph of the configuration is provided in [Fig. 13](#).

Segregation results are shown in [Fig. 14](#).

Fig. 13 Photograph of Jenike fluidized segregation apparatus.

Fig. 14 Weight percent retained on Funnel, Top, Middle and Bottom portions of Jenike Fluidized Segregator for Good and Bad lots.

As seen in the bar graph above a high percentage of the so-called "bad" lot is retained in the funnel portion. Photographs are shown in Fig. 15. The photographs of increased retention of material in the funnel portion for the so-called "bad" lot correlates with the reduced degree of particle size shift at higher aperture settings in aerodynamic dispersion and observations of increased cohesion in the so-called "bad" lot.

Fig. 16 shows the results of aeration permeability measurements on the previously presented "good" and "bad" lots as a function of applied normal stress, as measured by the air pressure drop across the powder bed. A less permeable powder bed (i.e., a

Fig. 15 At rest photographs of the funnel portion of the fluidized segregation results upon completion of the test for the “good” lot (left) and the “bad” lot (right).

Fig. 16 Pressure drop across powder bed and bulk density as a function of applied normal stress for the “good” and “bad” lots.

powder bed with a higher pressure drop) is more susceptible to unstable powder flow due to the inability to effectively displace powder volume with air. Despite the apparent divergence of the bulk density between the two lots under increasing normal stress, the ultimate convergence of the permeability of good and bad lots indicates that the pressure drop is inadequately explained by the densification of the powder bed. This shows that the “bad” lot (despite not being as dense relative to the “good” lot) is more vulnerable to challenges of powder flow from a storage bin due to the prohibitively high pressure drop at higher normal stresses.

Summary

The set of dynamic characterization techniques are presented above with the intent of conveying adjacencies to the aforementioned classical suite (the stock seven techniques described in the introduction) of characterizations performed on granular and powder raw materials. These are intended primarily to convey a nuanced understanding of granular or powder systems and not to convey a supposed “missing link”; indeed a concession of this work is that characterization of particulate materials for materials processing is highly dependent on the application and instances where the methods discussed above in detail may not be applicable. Conversely the stock seven techniques described earlier may similarly be parsed to glean useful information from the dynamic characterization techniques relevant to a given application.

Numerous other dynamic characterization techniques are available to obtain better understanding of an inorganic/organic batch system. Two examples not discussed above but highly relevant to powder systems include powder vibratory assisted auto agglomeration (Barletta and Poletto, 2012; Ku *et al.*, 2015), and powder vapor sorption characterization by non-aqueous sources (Arlabosse *et al.*, 2003).

Amorphous Materials: Vibrational Spectroscopy

PF McMillan, University College London, London, UK

© 2016 Elsevier Inc. All rights reserved.

This is a reprint of P.F. McMillan, Amorphous Materials: Vibrational Spectroscopy, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.03497-4.

Amorphous materials do not possess long-range order, so that understanding their structures at different length scales requires application of various diffraction and spectroscopic techniques, combined with computer modeling (Wong and Angell, 1976; Brawer, 1985; Rao, 2002; Mysen and Richet, 2005; Wang, 2013). Vibrational spectroscopy provides a detailed probe of molecular structure and bonding in amorphous solids and liquids as well as molecules and crystals (Nakamoto, 2009). Infrared (IR) spectroscopy and Raman scattering are the most convenient laboratory techniques for studying vibrational excitations in these systems (McMillan and Wolf, 1995). Inelastic neutron and X-ray scattering give additional information on the dynamics of disordered systems (Galeener *et al.*, 1983; Duffy, 2005; Greaves *et al.*, 2005; Haworth *et al.*, 2010). Molecular dynamics simulations and *ab initio* calculations give further insights into the nature of vibrations in glasses and liquids, as well as on relaxation processes (Brawer, 1985; Clark *et al.*, 1997).

IR and Raman Spectroscopy

In IR spectroscopy, a change in electric dipole moment ($\Delta\mu(t)$) associated with a vibrational mode of the sample interacts with the oscillating electric field ($E(t)$) of the incident IR beam, giving rise to an absorption signal. IR studies of amorphous materials are readily carried out using powder transmission, in which ground aliquots of sample are pressed into discs along with IR-transparent support material (nujol®, KBr), or by carrying out transmission experiments directly on thin films. Quantitative information on optical constants, including real and imaginary parts of the refractive index (n , k), dielectric constant (ϵ' and ϵ''), and the absorption coefficient $\alpha(\nu)$, is best obtained from IR reflectivity studies (Efimov, 1995).

Raman scattering spectroscopy is an inelastic light-scattering technique, in which the electric field (E_o) of the incident light oscillates at much higher frequency (ν^*) than the vibrational modes (ν_i). The incident light causes instantaneous displacements of the electron density relative to the nuclei, creating an induced dipole, $\vec{\mu}_{\text{ind}} = \alpha \vec{E}$: α is the molecular polarizability. For small vibrational displacements q_i ,

$$\mu_{\text{ind}}(t) = E_o \left(\alpha_o \cos 2\pi \nu^* t + \frac{1}{2} \left(\frac{d\alpha}{dq_i} \right)_o q_i \cos 2\pi (\nu^* \pm \nu_i) t \right)$$

The time-dependent terms result in re-emission of light not only at the Rayleigh-scattered incident frequency (ν^*), but also at Raman-shifted frequencies ($\nu^* - \nu_i$) and ($\nu^* + \nu_i$). Raman spectroscopy is carried out by passing a laser beam through the sample, and recording the vibrational spectrum of frequency shifts (usually $\nu^* - \nu_i$) expressed in wavenumber (cm^{-1}) units.

In addition to the features due to vibrational excitations, Raman spectra of glasses typically show a broad temperature-dependent low-frequency maximum that results from the combined T - and ν -dependence of the Raman scattering. At low frequency, amorphous materials show a near-continuum of vibrational states. The temperature dependence of the Raman scattered intensity gives rise to a multiplying factor which increases exponentially at small wavenumber. The two effects combine to give an apparent maximum in the Raman spectrum, which disappears if the sample is cooled well below room temperature, or if the spectra are 'reduced' by multiplying the observed intensities by the Bose factor $\nu/[n(\nu, T) + 1]$ ($n = 1/\exp(h\nu/kT) - 1$) (Daisenberger *et al.*, 2011). A distinct 'boson peak' feature is also found in inelastic scattering spectra of amorphous polymers and inorganic systems at low wavenumber values. This feature and its temperature dependence is indicative of the mesoscopic disordered structure of the glass (Shintani and Tanaka, 2008; Champagnon *et al.*, 2009). Excitations associated with the boson peak may play a role in defining the properties of the system at the glass transition (Angell, 1995; Greaves *et al.*, 2005). In resonance Raman spectroscopy, the incident laser excitation frequency corresponds nearly with electronic absorption transitions of the sample. The intensity of particular Raman-active modes is greatly enhanced, and the technique provides a powerful probe of local structure and vibrational-electronic coupling in the sample. Resonance Raman spectroscopy is used in studies of semiconducting glasses, for example, GeSe_2 or As_2S_3 (Wang, 2013).

Amorphous Tetrahedral Semiconductors

Vibrational excitations in amorphous semiconductors such as a-Si and a-Ge are studied primarily by Raman scattering spectroscopy (Tauc, 1975; Brodsky, 1983; Lucovsky and Pollard, 1984; Daisenberger *et al.*, 2011). The structures mainly consist of covalently bonded tetrahedral units, linked into a continuous random network (CRN). The Raman spectra have principal maxima at 460 cm^{-1} (a-Si) and 240 cm^{-1} (a-Ge), and resemble broadened vibrational density of states ($g(\nu)$) functions of the crystalline

semiconductors. This observation is due to loss of translational symmetry in the disordered semiconductors. The same process results in loss of inversion symmetry, and the vibrations of the amorphous solids are IR-active. Raman spectroscopy is highly sensitive for studying the onset of crystallization in a-Si or Ge, and for studies of disordering (due to, e.g., irradiation damage) of the crystals. Vibrational spectroscopy is useful for characterizing SiH_x and GeH_x sites in hydrogenated amorphous alloys (Lucovsky and Pollard, 1984; Vergnat *et al.*, 1993).

Disordered carbon-based materials have structures based upon sp²-bonded sheets as in crystalline graphite, which has its principal Raman mode at 1575 cm⁻¹. With increasing disorder, this band broadens and moves to ~1600 cm⁻¹, and a broad band at ~1355 cm⁻¹ grows in intensity. The result is interpreted as a gradual loss of crystalline selection rules and more of the crystalline phonon branches appear in the Raman spectrum as the average 'unit cell' becomes larger (Lespade *et al.*, 1982). Interpretation of the Raman spectra must take account of resonant effects appearing as a function of the incident laser wavelength (Ferrari and Robertson, 2001). The 1355 cm⁻¹ feature lies close to the Raman peak of tetrahedrally-coordinate diamond, and part of its intensity can be assigned to sp³-bonded regions in the structure using appropriate excitation (Ferrari and Robertson, 2001). Differences in band width, shape, and relative intensities of ~1600 and ~1355 cm⁻¹ features distinguish a-C samples with differing degree and type of disorder. Amorphous carbon nitride materials can be studied in a similar way (Ferrari *et al.*, 2003).

In amorphous III-V semiconductors, features in Raman and IR spectra are interpreted as broadened 'crystalline' *g*(*v*) functions within a CRN model, as for a-Si and -Ge. The a-(III-V) spectra show additional broadening due to separation of transverse and longitudinal modes in the polar semiconductor. The spectra also give information on local structure. In a-InP, a band near 440 cm⁻¹ is assigned to P-P linkages, revealing the presence of 'wrong bonds' in the amorphous semiconductor. a-Si_xGe_{1-x} alloys show features near 500, 250, and 370 cm⁻¹, assigned to Si-Si, Ge-Ge, and Si-Ge bonds (Lucovsky and Pollard, 1984). The relative intensities vary systematically with Si:Ge ratio. This example of 'two-mode' behavior demonstrates how the CRN 'density of states' model for a-Si and a-Ge is extended to a more local, 'molecular,' interpretation, in intermediate compounds. Raman spectra of a-Si_xC_{1-x} samples show bands at 525 and 1430 cm⁻¹, assigned to Si-Si and C-C bonds in the sample. In this case, the C-C bonding is planar sp², unlike the tetrahedral sp³ bonding of the a-Si network.

Chalcogenide Glasses

The second large family of amorphous semiconductors is that of amorphous chalcogenides (X=S, Se, Te), and their binary (GeS_x, AsS_x), ternary, and more complex (Ge-As-X, etc.) compounds. These have applications as IR transmitting optical materials due to the low vibrational frequencies associated with the heavy atoms and relatively weak interatomic bonding present (Lucas, 1999; Wang, 2013). Liquid S just above its melting point shows a rich Raman spectrum with peaks at 474, 218, 151, and 77 cm⁻¹ (Brodsky, 1983). The spectrum resembles that of the orthorhombic crystal, with 'isolated' S₈ ring units held together by van der Waals forces. The Raman spectrum of the liquid is thus given a 'molecular' interpretation, contrasting with the CRN interpretation of a-Si and a-Ge. As temperature is increased, the S₈ chains begin to open into S_n polymeric chain units, and the viscosity increases. The Raman spectrum of a-Se is dominated by a band at 235 cm⁻¹, with a prominent shoulder at 255 cm⁻¹. These features correspond to the Se-Se stretching peaks of the trigonal (helical Se_∞ chains) and monoclinic (Se₈ rings) crystalline forms. The IR spectrum shows pairs of bands in the 220–260 cm⁻¹ and 90–150 cm⁻¹ ranges, assigned to Se-Se stretching and bending modes within chain and ring units. The glass consists of Se_n chain units with some proportion of Se₈ rings. In the case of a-Te, the Raman spectrum is dominated by a broad band at ~160 cm⁻¹, with a weaker feature appearing at ~85 cm⁻¹. Although the spectrum is usually given a 'density of states' interpretation like a-Si, it does not correspond to a broadened *g*(*v*) function for known crystalline forms of Te.

Crystalline As₂S₃ and As₂Se₃ have planar structures containing pyramidal AsX₃ (X=S,Se) units linked by bridging X atoms. The Raman spectrum of a-As₂S₃ has a strong, polarized band at 360 cm⁻¹ due to As-S stretching, whereas the IR spectrum is dominated by a band at 310 cm⁻¹. The complementarity between IR and Raman spectra indicate that the pyramidal AsX₃ molecular units have high symmetry. The units vibrate 'independently' because the AsXAs angle is narrow (90°–100°). The polarized Raman band is assigned to symmetric (*v*₁) AsS₃ breathing, and the IR band to asymmetric (*v*₃) stretching. Weaker features at 130–150 cm⁻¹ range are due to bending vibrations.

A CRN 'density of states' interpretation could equally well be applied to a-As₂S₃ and a-As₂Se₃, in that the glass spectra resemble broadened *g*(*v*) functions derived from the crystalline materials. This observation illustrates convergence between the two 'extreme' models for interpreting spectra of amorphous materials. When phonon branches show little dispersion, as in c-As₂S₃, they correspond to 'localized' vibrational excitations, and they give rise to sharp peaks and rich structure in the vibrational spectra of the amorphous material that are readily interpreted in terms of 'molecular' structures. When crystal dispersion is large, as is the case in c-Si and c-Ge, a range of frequency-dependent coherence lengths occurs in the corresponding amorphous material, and detailed information on local 'molecular' structure is difficult to extract from the vibrational spectra.

In binary As-S glasses, Raman and resonance Raman studies reveal the presence of As-As (peak at 231 cm⁻¹) and S-S (490 cm⁻¹) linkages, including S₈ ring units at high sulfur content. The glasses contain As₄S₄ molecular units, identified by their spectroscopic signature peaks at 220 and 190 cm⁻¹. These units undergo light-initiated polymerization upon prolonged exposure to the laser beam.

Amorphous GeX₂ (X=S, Se, Te) systems consist essentially of tetrahedral GeX₄ units linked by two-coordinated X atoms, as in the crystalline materials. a-GeSe₂ shows a strong, polarized Raman mode at 342 cm⁻¹, assigned to symmetric stretching (*v*₁) of GeS₄

groups in the structure. The corresponding ν_3 mode (asymmetric stretching) is found in the IR spectrum at 367 cm^{-1} . In $\text{Ge}_x\text{S}_{1-x}$ glasses with $x > 0.67$, the characteristic Raman mode of S_8 rings (470 cm^{-1}) is observed in the spectra, confirmed by IR data. At high Ge concentrations, broadening of the Ge–S stretching band and increased intensity in the 300 cm^{-1} region reveals the formation of Ge–Ge linkages in partly substituted $\text{Ge}(\text{Ge,S})_4$ tetrahedral units.

Silicate and Aluminosilicate Glasses

This large class of amorphous materials is significant for geology as well as glass science (Wong and Angell, 1976; McMillan and Wolf, 1995). $\alpha\text{-SiO}_2$ consists of a 3-D network of corner-shared SiO_4 tetrahedra. The vibrational spectrum measured by neutron scattering resembles $g(\nu)$ of crystalline SiO_2 polymorphs, and is dominated by broad bands at ~ 1100 , 800 , and 350 cm^{-1} (Galeener *et al.*, 1983; Figure 1). The Raman and IR spectra contain similar bands, assigned to Si–O stretching and OSiO, SiOSi bending vibrations within the tetrahedral network. Much discussion has been concerned with the cooperative nature (i.e., correlation length) of these excitations. Hyper-Raman experiments indicate that the highest frequency modes are highly localized, but vibrational coherence exists for the lowest frequency excitations, from neutron studies. The Raman spectrum contains sharp peaks at 606 and 492 cm^{-1} that are not predicted by structural models based on known polymorphs. These features are due to 3- and 4-membered siloxane rings present as ‘defect’ species within the glass. Their formation enthalpies are $\sim 42\text{ kJmol}^{-1}$ and $\sim 15\text{ kJmol}^{-1}$, and the Raman intensities are a useful indicator of the state of thermal equilibration of the glass. Ring formation has a negative ΔV , so that the 3-ring peak intensity increases both with density, and also in glasses prepared from gels or from the vapor phase. The Raman spectrum is dominated by a polarized 430 cm^{-1} band due to symmetric SiOSi bending in intertetrahedral linkages. The frequency is dependent upon intertetrahedral (SiOSi) angle, and it shows anomalous behavior with temperature due to anharmonicity below the glass transition and structural relaxation at high temperature.

Adding alkali or alkaline earth metal oxide components (M_xO_y) to SiO_2 causes depolymerization of the framework and ‘non-bridging oxygens’ (NBO) appear with increased O:Si ratio. Silicon is a strong Lux-Flood acid, so that all O atoms are usually bound to at least one Si. Exceptions include Pb–O–Pb linkages occurring in lead silicate glasses and liquids and Al–O–Al linkages in aluminosilicates (characteristic Raman peaks at ~ 200 and $\sim 570\text{ cm}^{-1}$). Changing polymerization of the silicate framework results in the successive appearance of silicate units with 1, 2, 3, and 4 NBO, labeled Q^n ($4 - n$ is the number of NBO present). Characteristic Raman peaks at ~ 1100 , 1000 , 900 , and 850 cm^{-1} are assigned to symmetric Si–O stretching vibrations of Q^3 , Q^2 , Q^1 , and Q^0 species. Coexistence of Q^n species at a given composition in equilibria like $2\text{Q}^3 = \text{Q}^4 + \text{Q}^2$ is studied by Raman and NMR spectroscopy. The reactions are endothermic, with $\Delta H^\circ \sim 15\text{--}30\text{ kJmol}^{-1}$. In IR reflectance, the strong SiO_2 glass band at $\sim 1150\text{ cm}^{-1}$ decreases rapidly in reflectivity with added ‘modifier’ oxide component, accompanied by the growth in intensity of a band near 1075 cm^{-1} . This band shifts to lower frequency as SiO_2 is decreased, and it is joined by a second component at $1000\text{--}900\text{ cm}^{-1}$. These features correspond to asymmetric Si–O stretching in structures dominated by Q^3 and Q^2 . Features at $800\text{--}900\text{ cm}^{-1}$ in spectra of glass compositions with lower silica contents are due to asymmetric stretching of Q^1 and Q^0 species.

The vibrational bands of aluminosilicate glasses are broader than for silicates because of a greater distribution in structural environments, and the perturbing effect of Al on silicate vibrations. ‘Charge-balanced’ $\text{SiO}_2\text{--MAl}_2\text{O}_4$ ($\text{M} = 2\text{M}^+$ or M^{2+}) glasses have structures based on a polymerized network of SiO_4 and AlO_4 . Mg-containing glasses have very broad spectra, and contain five- and six-coordinated Al. The spectra between 850 and 1250 cm^{-1} contain unresolved bands due to (Si,Al)–O stretching vibrations of the tetrahedral framework: components are assigned to ‘ $\text{Q}^4(n\text{ Al})$ ’ species, in which SiO_4 tetrahedra share up to four linkages with Al atoms. At high SiO_2 content, Raman spectra indicate that clustering of Al-rich domains occurs, consistent with positive deviations from ideality found in heats of mixing in M^{2+} -bearing systems. IR and Raman bands at $400\text{--}600\text{ cm}^{-1}$ region are assigned to TOT or OTO ($\text{T} = \text{Si, Al}$) bending.

Pure aluminates are highly ‘fragile’ (non-Arrhenian) liquids that are marginal glass formers (Angell, 1995). $\text{CaO}(\text{Ga,Al})_2\text{O}_3$ bulk glasses and fibers are useful IR-transmitting materials. The three-dimensional network of corner-linked AlO_4 tetrahedra in CaAl_2O_4 is analogous to SiO_2 , ‘stuffed’ with Ca^{2+} ions. The Raman spectrum contains a strong polarized band at 580 cm^{-1} due to AlOAl bending. The band is sharper than its counterpart in SiO_2 because the range in intertetrahedral angles is smaller (average AlOAl angle $\sim 135^\circ$). For $\text{CaO}:\text{Al}_2\text{O}_3 > 1$, Raman and IR spectra indicate depolymerization of the tetrahedral network analogous to binary silicates. In glasses with $\text{CaO}:\text{Al}_2\text{O}_3 < 1$, AlO_5 and AlO_6 species appear, and extreme broadening of vibrational spectra occurs. Similar broadening is found in Raman and IR spectra of $\text{SiO}_2\text{--Al}_2\text{O}_3$ glasses. Here, the Raman signature of SiO_2 -rich regions is superimposed on a background due to the featureless vibrational ‘density of states’ of an alumina-rich matrix, consistent with the observation of unmixing in the system.

Carbonate and Nitrate Glasses

Carbonate glasses are mainly studied because of their importance for understanding geochemically important carbonatite magmas (Genge *et al.*, 1995) whereas nitrate compositions are well known ‘marginal’ glass formers (Angell, 1995). IR and Raman spectroscopy show that the glasses are based upon the CO_3^{2-} anion, and that different types of carbonate environment exist within the glass. Similar IR and Raman studies show that nitrate glasses (e.g., $\text{KNO}_3\text{--Ca}(\text{NO}_3)_2$) contain NO_3^{2-} anions. The

Figure 1 Comparison of the inelastic neutron scattering (a), polarized (HH and HV) Raman (b), and IR reflectance (c), spectra of SiO₂ glass. The sharp 'defect' peaks at 500 and 600 cm⁻¹ are clearly visible in the HH Raman spectrum. The strongly IR-active modes above 1000 cm⁻¹ are assigned to tetrahedral Si–O stretching vibrations: the highly polarized Raman band at 430 cm⁻¹ is assigned to symmetric SiOSi linkage bending vibrations. Adapted from Galeener, F.L., Leadbetter, A.J., Stringfellow, M.W., 1983. Comparison of the neutron, Raman, infrared vibrational spectra of vitreous SiO₂, GeO₂, BeF₂. *Physical Review B* 27, 1052–1078.

Raman-active symmetric stretching (ν_1) vibration is particularly characteristic of the trigonal planar units. IR and Raman spectroscopy can detect small concentrations (>50 ppm) of these species dissolved in glass.

Borate and Phosphate Glasses

Glasses based upon B₂O₃ form a large class of technologically important materials (Konijnendijk, 1975; Wong and Angell, 1976). The Raman spectrum of α -B₂O₃ is dominated by a narrow, polarized band at 808 cm⁻¹ due to symmetric breathing of B₃O₃ 'boroxol' rings within the glass structure based upon linked trigonal BO₃ units. The IR spectrum shows a strong band at ~1250 cm⁻¹, due to B–O stretching, and a weaker band at ~700 cm⁻¹ due to OBO/BOB bending. As metal-oxide 'modifier' component is added to B₂O₃, the boroxol ring peak in the Raman spectrum is replaced by a feature at ~770 cm⁻¹ and broad B–O stretching vibrations at 1400–1500 cm⁻¹ become prominent. These changes indicate the appearance of tetrahedral BO₄ groups in the glass. The structures of alkali and alkaline earth borosilicate and boroaluminate glasses have been investigated using Raman and IR spectroscopy. In borosilicates close to a 'charge balanced' join (SiO₂-M⁺BO₂), the glass structures are analogous with

aluminosilicates, with tetrahedral B^{3+} replacing Si^{4+} in the network. For ternary glasses with high B_2O_3 contents, the boroxol ring peak becomes prominent in the spectra indicating the presence of BO_3 units.

Phosphate glasses have applications in biomedicine, in high-power lasers, and in semiconductor packaging. Hygroscopic $\alpha-P_2O_5$ has a network structure based on tetrahedral PO_4 , in which three oxygens are bridging (POP linkages) and the fourth is terminal ($P=O$). The Raman spectrum is dominated by a polarized narrow band at 1390 cm^{-1} due to $P=O$ stretching, and strong IR and Raman bands in the $650\text{--}800\text{ cm}^{-1}$ region characteristic of POP linkages. Bulk glasses and fibers are easily formed from melts around the metaphosphate ($-PO_3^{2-}$) to pyrophosphate ($P_2O_7^{4-}$) compositions. Metaphosphates are based upon chains of PO_4 tetrahedra, with two bridging oxygens and two NBO per tetrahedron (i.e., $=PO_2$ units). The IR and Raman spectra show peaks at $1100\text{--}1200\text{ cm}^{-1}$ and $\sim 700\text{ cm}^{-1}$ due to $P-O$ stretching and POP bending, respectively. The width and frequency of each peak is sensitive to the number and type of counter ion present. Low-frequency (far-IR) peaks are due to characteristic cation modes decoupled from the phosphate glass framework (Exarhos, 1983). Vibrational spectroscopy is useful in studies of phase separation and fluorine incorporation in silicophosphate glasses for laser applications. Characteristic $P-F$ and $Si-F$ stretching vibrations are observed in the $750\text{--}900\text{ cm}^{-1}$ region of the spectra.

Fluoride Glasses

$\alpha\text{-BeF}_2$ has a tetrahedral network structure based upon tetrahedral BeF_4 units linked by bridging F^- ions (Galeener *et al.*, 1983; Brawer, 1985). Fluorides based upon fluorozirconate (ZrF_4) and fluorohafnate (HfF_4) components give rise to a wide range of binary ($ZrF_4\text{--}BaF_2$), ternary ($ZrF_4\text{--}BaF_2\text{--}NaF$: ZBN), and complex ($ZrF_4\text{--}BaF_2\text{--}LaF_3\text{--}NaF$: ZBLAN) glass-forming compositions with applications as IR-transmitting fibers (Lucas, 1999). The liquids are highly fragile (Angell, 1995), and vibrational spectroscopy is used to study changes in glass and liquid structure with temperature and composition (Simmons *et al.*, 1991; Aasland *et al.*, 1996). Fluorozirconate glasses and liquids have structures containing Zr polyhedra in 6-, 7-, and 8-fold coordination, linked by bridging F^- ions. The 'doubly-bridged' $Zr(F,F)\text{--}Zr$ unit formed by edge sharing between adjacent ZrF_n polyhedra is also important. Systematic variations in glass properties with composition are explained by changes in the Zr coordination and the relative numbers of bridging and non-bridging fluorines.

The main Raman peak at $570\text{--}590\text{ cm}^{-1}$ is assigned to symmetric stretching (ν_s) of terminal $Zr\text{--}F$ bonds within ZrF_n polyhedra. The IR band at $490\text{--}520\text{ cm}^{-1}$ is due to asymmetric (ν_{as}) $Zr\text{--}F$ stretching, involving bridging and non-bridging fluorines. The Raman bands at $330\text{--}490\text{ cm}^{-1}$ are assigned to $Zr\text{--}F$ stretching within $Zr\text{--}F\text{--}Zr$ linkages. The lowest frequency bands ($180\text{--}200\text{ cm}^{-1}$ in the Raman spectrum, and $250\text{--}285\text{ cm}^{-1}$ in the IR spectrum) are assigned to ZrF_n bending vibrations, as well as counter-cation vibrations.

The stretching frequencies (ν_s and ν_{as}) in fluorozirconate glasses occur at lower frequency than in corresponding melts, indicating that the average Zr coordination number is greater in the glass. This is achieved by increased formation of $Zr\text{--}F\text{--}Zr$ linkages on vitrification. The rapid structural change with temperature is used to rationalize the extreme fragility in these systems. Both ν_s and ν_{as} frequencies also decrease with increasing F/Zr ratio for glasses and melts. This observation indicates increased average $Zr\text{--}F$ distance, as shorter, stronger terminal $Zr\text{--}F$ bonds are replaced by longer $Zr\text{--}F\text{--}Zr$ bridges associated with increased Zr coordination and degree of polymerization (Aasland *et al.*, 1996).

The Origin of NMR Spectroscopy

The first successful observation of a NMR signal was in 1945. There were two groups of physicists working independently: Bloch, Packard and Hansen (Stanford University) observed a signal from the protons of water, and Purcell, Torrey and Pound (Harvard University) detected a signal from the protons in paraffin wax. In 1952 Bloch and Purcell were awarded the Nobel Prize for physics for this outstanding discovery (Iggo, 2000).

Nuclear spin arises from unpaired proton and neutron spins in the nucleus. It depends on the number of protons and neutrons of it. Only nuclei with non-zero spins ($I \neq 0$) can absorb and emit electromagnetic radiation and induce observed "resonance". There are some rules for the determination of nuclear spin (I), which are listed in Table 1. If the mass number of the element is odd, it has half spin. If the mass number is even, the nuclear spin depends on the numbers of protons and neutrons. Both numbers being even result in spin-zero, while spin is an integer when the number of protons and neutrons is odd (Iggo, 2000). One of the distinguishing features of NMR is that its signals are isotope-specific. For example, ^{12}C is spin-zero and does not have a NMR signal, but ^{13}C is spin half and can be studied by NMR. Due to the isotope-specificity, the natural abundance of each isotope plays an important role in the NMR experiment. Using ^{12}C and ^{13}C as an example again, the zero-spin ^{12}C isotope has a natural abundance of nearly 99%, and which means the NMR visible ^{13}C is only 1.1% abundant. This results in only 1% carbon atoms contributing to the NMR signal. Therefore, ^{13}C NMR experiments need a much longer signal acquisition time due to this. Nuclear spin values ranging from $I = 0$ to $I = 8$ in 1/2-unit increments can be found across the entire periodic table. These are listed in Support materials Table 1 (Paralla, 1998).

The number of protons is equal to the atomic number of the isotope, and the number of neutrons is calculated by atomic mass minus atomic number. Fig. 1 is an example of how to determine the number of proton and neutrons of ^{23}Na (Paralla, 1998).

When a nucleus is placed in a magnetic field, the spinning generates a magnetic moment μ . The moment is proportional to the spin I ; the proportionality constant is named the gyromagnetic ratio γ . Every isotope has its different gyromagnetic ratio, which also gives it a unique magnetic moment. That is why each isotope has a characteristic NMR resonance frequency. High gyromagnetic ratios correspond to high NMR sensitivity. The origin of NMR spectroscopy comes from the nuclear spin interaction with a magnetic field. When putting a nucleus in an external magnetic field, the nuclear magnetic moment will have different orientations. However, only certain orientations with respect to the applied field direction are allowed due to the nuclear spin I being quantized. Each orientation corresponds to a quantum number m_I which can take integer or half-integer values depending on the number of unpaired protons and neutrons, and there are $2m_I + 1$ orientations allowed, which correspond to $2m_I + 1$ discrete energy levels. This is called Zeeman splitting. The energy of each level depends on the applied magnetic field, nuclear magnetic gyromagnetic ratio γ and the orientation of the nuclear magnetic moment to the applied field m_I . Due to both γ and m_I being intrinsic features of each isotope, the energy change of the transition between the different energy levels can be used to identify each element. The transition between the nuclear spin energy levels can be excited by irradiating the nuclear magnetic moment at the Larmor frequency (see Eq. (4) below). However, according to the selection rules, not all the transitions are allowed, only $\Delta m_I = \pm 1$ can happen, for example, spin $I = 1/2$ has two energy levels ($2m_I + 1 = 2 \times \frac{1}{2} + 1 = 2$): $m = +1/2$ and $m = -1/2$. It is convention to name energy level $+1/2$ as spin up (α) and $-1/2$ as spin down (β), $\Delta m = -1/2 - (+1/2) = -1$, therefore, the transition from α to β is allowed. The energy of the allowed transition is given in Eq. (1) (Iggo, 2000).

$$\Delta E = E_\beta - E_\alpha = -m_\beta \left(\frac{h}{2\pi} \right) \gamma B_0 - \left(-m_\alpha \left(\frac{h}{2\pi} \right) \gamma B_0 \right) = \left(\frac{h}{2\pi} \right) \gamma B_0 \quad (1)$$

Where h is Planck's constant ($6.62607 \times 10^{-34} \text{ m}^2 \text{ kg s}^{-1}$), B_0 is the magnetic field strength (T), and γ is the gyromagnetic ratio ($\text{rad. s}^{-1} \cdot \text{T}^{-1}$). This energy gap corresponds to the frequency of the photon as shown in Eq. (2) (Iggo, 2000)

$$E = h\nu \quad (2)$$

So the transition is at the frequency (Hz)

$$\nu = \frac{\Delta E}{h} = \frac{\gamma B_0}{2\pi} \quad (3)$$

The definition of Larmor frequency is

$$\nu_0 = -\frac{\gamma B_0}{2\pi} \quad (4)$$

In conclusion then, for a single spin, there is one allowed transition which results in resonance at minus the Larmor frequency in the spectrum (Keeler, 2010).

The basic NMR experiment is conducted as follows. When a sample is placed in a spectrometer field, it takes time to build up bulk magnetization along the z-axis, which is the equilibrium magnetization stage; typically this delay is the order of a few

Table 1 Rules for determination of nuclear spin (I)

Mass number	Number of Protons	Number of neutrons	Spin (I)	Example
Odd	Even	Odd	Half-Integer (1/2, 3/2...)	^{13}C
	Odd	Even	Half-Integer (1/2, 3/2...)	^{23}Na
Even	Even	Even	0	^{12}C , ^4He , ^{16}O and ^{32}S
	Odd	Odd	Integer(1,2 ...)	^2H

seconds. In the second stage, a very short burst of high power RF, lasting no more than 20 μs is applied, this excites a transient signal, known as free induction decay (FID), which is then recorded for a time called the acquisition time, which usually lasts between 50 ms and a few seconds. Finally, the time-domain signal that NMR spectroscopy measures is transformed to a frequency-domain signal, which we are more familiar with, by Fourier transformation. The FID signal can be considered as arising from a vector of length M_0 rotating at frequency Ω ; the x and y components of the vector give M_x and M_y , which shown in Eq. (5) (Keeler, 2010).

$$M_x(t) = M_0 \cos \Omega t \text{ and } M_y(t) = M_0 \sin \Omega t \quad (5)$$

As a consequence of the way the Fourier transform works, it regards $M_x(t)$ and $M_y(t)$ as the real and imaginary parts of a complex signal $S(t)$ (Eq. 6). We are not concerned too much with the mathematical details here (Keeler, 2010)

$$S(t) = S_x(t) + iS_y(t) = M_0 \cos \Omega t + iM_0 \sin \Omega t = M_0 \exp(i\Omega t) \quad (6)$$

In an NMR experiment, the signal also decays over time due to the transverse magnetization. This decay can be represented by an exponential decay with a time constant T_2 , and Eq. (7) gives the frequency domain signal, which produces the spectrum (Keeler, 2010).

$$S(t) = M_0 \exp(i\Omega t) \exp\left(\frac{-t}{T_2}\right) \quad (7)$$

If the size of FID increases, the signal height of the resonance increases in direct proportion, which means by integrating the lines in the spectrum, the relative number of protons contributing to the lines can be determined.

In Eq. (4), the resonance frequency, ν , is related to the applied magnetic field, B_0 . In the early days of NMR, resonance was detected by varying the applied field B_0 . In order to avoid the confusion of different NMR results being produced by different magnetic fields, in 1972, IUPAC recommended the convention of resonance frequency for sample X ($\nu_{X, \text{sample}}$) being reported as its chemical shift ($\delta_{X, \text{sample}}$) (Eq. 8) (Keeler, 2010). For convenience, the chemical shift is reported in ppm (parts per million), and the simple conversion from measured frequencies to chemical shift in ppm is shown in Eq. (9) (Keeler, 2010)

$$\delta_{X, \text{sample}} = \left(\frac{\nu_{X, \text{sample}} - \nu_{X, \text{reference}}}{\nu_{X, \text{reference}}} \right) \times 10^6 \quad (8)$$

$$\delta_{X, \text{sample}} / \text{ppm} = \frac{(\nu_{X, \text{sample}} - \nu_{X, \text{reference}}) / \text{Hz}}{\nu_{X, \text{reference}} / \text{MHz}} \quad (9)$$

Fig. 2 Illustration of tree diagram for (a) J coupling of two spins (b) J coupling of three spins.

Fundamental Effects in NMR

The energy levels involved in NMR spectroscopy arise from the interaction of the nuclear spin with the magnetic field. However, the real magnetic field which the nucleus experiences is not the same as the applied field. There are three additional fields could be involved in the NMR spectroscopy, which provide more structure information.

(1) Chemical shielding

Chemical shielding arises from the electrons near the nucleus. When the charged electrons move in the molecular orbitals, in the applied magnetic field, they produce an induced field surrounding the nucleus. If the induced field opposes the spectrometer field, the nucleus will experience a smaller magnetic field; so the electrons are said to shield the nucleus. When the induced field has the same direction as the applied field, it reinforces the spectrometer field, and the nucleus is said to be deshielded. The additional field due to electron motion depends on the bonding elements and the type of bonding. So chemically different groups of nuclei will experience different shielding effects and generate different resonance frequencies. This is chemical shielding. The magnitude of chemical shielding depends on the strengths of the applied field. Since not every laboratory uses the same magnets, even the same chemical shielding might give a different resonance frequency. So to avoid confusion, the chemical shift is reported as the shift of the resonance line position from that of a reference compound, i.e., as a chemical shift.

(2) J coupling

Coupling arises because the nuclear magnetic moments of other nuclei surrounding the nucleus under analysis produce extra magnetic fields. It only depends on the interaction of coupled nuclei, so the magnitude of J-coupling does not vary with the applied field, and the unit of the J-coupling constant is Hertz. J-coupling is through chemical bonds, and it diminishes with an increasing number of bonds between two coupling nuclei. Usually with J-coupling, more than four bonds are too weak to be detected. The information related to J-coupling can be used to map the bonding framework of the molecular structure. The presence of J-coupling gives rise to multiplets in the spectrum. The form of these multiplets can be predicted by tree diagrams, which are shown in **Fig. 2** (Keeler, 2010). At the top, there is one spin and its resonance is ν_1 , in **Fig. 2(a)**, there is a doublet, which is the spin one splits symmetrically into two, one shifted by $\frac{1}{2}J_{12}$ to the left and another one shifted to the right by $\frac{1}{2}J_{12}$. These split lines correspond to the second spin being in the up and down spin states. In **Fig. 2(b)** a third spin is introduced, each line from the second spin is split symmetrically into two and shift by $\frac{1}{2}J_{13}$. The results are four-line multiplets.

However, sometimes a 1D spectrum could be obscured by overlapping multiplets, the more straightforward coupling map can be obtained by 2D spectra. The most popular 2D J-coupling experiments involve COSY (correlation spectroscopy) which is for homonuclear interaction, and for heteronuclear there are HMBBC (heteronuclear multiple-bond correlation) and HMQC (heteronuclear multiple-quantum correlation). TOCSY (total correlation spectroscopy) can be used to detect an unbroken J-coupling chain (Ashbrook and Duer, 1995).

(3) Relaxation

By giving radiofrequency pulses, the magnetic moment will move from the longitudinal plane (z axis) to the transverse plane (xy axis). When the RF pulses are switched off, the magnetic moments will return to their original position. This process is called relaxation. There are two types of relaxation: T_1 and T_2 . T_1 relaxation, also known as longitudinal relaxation or spin-lattice relaxation, which is when the z-magnetization, is returned to its equilibrium value and transfers its RF energy to its surrounding environment non-radioactively. It is the process by which the system re-establishes the Boltzmann equilibrium. T_1 relaxation is thus related to z-magnetization. When T_1 relaxation occurs, the longitudinal magnetization increases. T_2 relaxation is related to the xy-plane. When the magnetic moment is excited, the magnetic moments in xy plane are in phase. Once the RF is switched off, the in-phase spin experiences the field change and becomes out of phase. This is so-called dephasing. There are two modes by which T_2 relaxations arise. A non-secular part is contributed by the fluctuation in the local magnetic fields when the magnetic

Table 2 Relaxation properties

<i>Spin number</i>	<i>Magnetic properties</i>	<i>Relaxation properties</i>	<i>Isotopes</i>
1/2	Large magnetogyric ratio	Short T_1	^{133}Cd ^{199}Hg
1/2	Small magnetogyric ratio	Long T_1	^{57}Fe ^{103}Rh
> 1/2	Large magnetogyric ratio	Short T_2	^{51}V ^{53}Cr
> 1/2	Small magnetogyric ratio	Very short T_2	^{55}Mn ^{59}Co

moment reorients to the equilibrium position. A secular part is a relatively small change in the amount of the local field arising due to z-magnetization change. T_2 relaxation is also known as spin-spin relaxation. The spin exchange could be faster than the Boltzmann equilibrium so $T_2 \leq T_1$. The relaxation occurs when the nuclear spin within a magnetic field is near the Larmor frequency. This field could arise from other nuclei spins (dipole-dipole relaxation), unpaired electron spins and nuclear quadrupolar interaction (quadrupolar relaxation). Isotopes with spin = 1/2 exhibit sharp resonance while those with spins ≥ 1 show very broad lines due to the short T_2 . [Table 2](#) lists the relaxation properties of some isotopes.

The relaxation is an important effect in NMR and can give useful structural information. Because the relaxation is through space, it can be used to study the neighboring nuclei and to determine molecular conformation. The popular experiments to study relaxation are NOESY (Nuclear overhauled effect spectroscopy) and ROESY (Rotation frame nuclear-overhauled effect spectroscopy) ([Ashbrook and Duer, 1995](#)).

The Spectrometer

Available spectrometers are complex instruments. The basic components include a magnet, a probe, a transmitter, a receiver, a digitizer, and a computer to control everything and a pulse programmer to produce timed pulses and delays. A simplified diagram of an NMR spectrometer is shown in [Fig. 3](#) ([Rankin et al., 2014](#)).

The magnet in the modern NMR spectrometer is a superconducting magnet which generates an intense, homogeneous and stable magnetic field B_0 . The magnet is wrapped by a coil of wire, and when current passes through the coil, a magnetic field is generated. As the coil is superconducting, the resistance of the coil is zero. Thus, an electric current passing through the superconducting coil can persist forever and generate a stable magnetic field without consuming any powder. The coil has to be immersed in a bath of liquid helium in order to maintain the superconducting state. This liquid helium bath also needs to be surrounded by a bath of liquid nitrogen as a “heat shield”. In [Fig. 3](#), the vertical tube passing through the magnet is called the bore tube, which is a room temperature region in which to put a finely powdered sample in the magnetic field ([Keeler, 2010](#)).

The probe is inserted into the bore of the magnet and consists of a small coil to excite and detect the NMR signal and various other electronic components designed to heat or cool the sample. The typical arrangement of the RF transmitter includes a synthesizer which produces the RF output. This low level RF passes the gate and an attenuator to a high-power amplifier. Switching on or off of the RF is controlled by the gate, and the input of the amplifier is controlled by the attenuator. The amplifier boosts the controlled input RF and creates hard pulses. Therefore the RF transmitter is capable of delivering short high-power pulses, and longer low-power pulses for selective excitation.

The receiver is used to capture and amplify the NMR signals. The signal from the probe is very small; thus, the very sensitive receiver is usually placed as close to the probe as possible and, more importantly, it needs to be designed to minimize any noise. The voltage signal from the receiver is converted to a binary number and stored in the computer by an analog to digital converter (ADC) which represents the FID as data points. The pulse programmer is used to produce precisely timed pulses and delays. Usually, the acquisition of data is also executed by a pulse programmer ([Keeler, 2010](#)).

The Basics of MRI

MRI (magnetic resonance imaging) is an imaging technique used primarily in medical settings to produce high-quality images of the inside of the human body. MRI examination is widely used for brain, spinal cord, musculoskeletal, abdominal/pelvic, cardiovascular, mammographic and pregnancy examinations. MRI is based on the principles of NMR. When the human body is placed in a strong magnetic field, the collective effect of vast numbers of hydrogen nuclei produces a net tissue magnetization. Each

Fig. 3 Illustration of the NMR spectrometer. Reproduced with permission from Rankin, N.J., *et al.*, 2014. The emergence of proton nuclear magnetic resonance metabolomics in the cardiovascular arena as viewed from a clinical perspective. *Atherosclerosis* 237 (1), 287–300. Available at: <https://doi.org/10.1016/j.atherosclerosis.2014.09.024>. Copyright (2014), Elsevier, Ireland Ltd.

MRI image consists of a T_1 component and a T_2 component. In a T_1 weighted sequence, the contrast of the image is determined by the difference in T_1 relaxation time between fat and water. Fat is white in the resulting image as it has a high signal intensity, while water is black in the image. T_1 weighted imaging is preferred in musculoskeletal system checks because the fat-containing bone marrow gives high signal intensity and any bone marrow edema or bone marrow infiltration can be captured easily. In a T_2 weighted sequence, the fluid-containing part is highlighted; thus, it is suitable to detect pathology. Whether to use T_1 or T_2 weighted images, is decided as a general rule by the fluid-filled structure. The fluid has a high signal intensity on T_2 weighted image and is a more reliable marker than fat (Hendrick, 2008).

Solid State MAS NMR

One significant disadvantage of static solid state NMR compared to solution NMR, is the resultant broad and symmetric resonance, which is caused by the fixed molecular orientations arising in the solid state. The interaction between the nuclear spin and applied field depends on the angle between them. In solution NMR, this angular dependence is averaged out by the fast molecular tumbling in solution samples. There are two interactions in solid-state NMR which have line broadening effects. These are:

(1) Shielding Anisotropy

If the distribution of electrons around the nucleus is not isotropic, it gives rise to anisotropic shielding of the nucleus, which generates a non-symmetric NMR lineshape.

(2) Dipolar interaction

In the solid sample, the dipolar interaction through space can be very large. This increases the line width of NMR resonances.

However, both interactions depend on the geometric factor, $3\cos^2\theta = 1$, i.e., for $\theta = 54.74^\circ$. This is the so-called magic angle. When the sample spins at 54.74° to the magnetic field, the effects of shielding anisotropy and dipolar interaction on the line broadening are much diminished (Iggo, 2000). As a result, MAS NMR is a powerful tool for inorganic materials structure characterization. The commonly used pulse program is CP (cross-polarization). It is used to transfer spin polarization from the protons with abundant spins to less sensitive nuclei. This high power decoupling aims to eliminate dipolar coupling between proton spins and the nucleus under observation.

MAS NMR Studies of Ceramics and Glasses

MAS NMR has been successfully used to investigate the structure of various glasses, glass-ceramics and ceramics. It is a powerful tool to probe the chemical bonding and local chemical structure. In a comparison to another commonly used structure characterization technique, XRD (X-Ray Diffraction), NMR can be used to study both amorphous and crystalline materials, whereas XRD is only able to give information about the lattice structure of crystalline materials. NMR analysis is also able to focus on the local structure or nearest neighbor bonding, which makes it extremely useful when similar atomic weight cations or anions are substituted into a structure. This is sometimes difficult to prove by XRD pattern analysis, but can be easily detected by the chemical shift of the bonding nucleus in NMR. ^{29}Si , ^{31}P , ^{19}F , ^{27}Al MAS NMR spectroscopy are commonly used to study ceramics and glasses and examples of the application of MAS NMR to the study of these materials are now discussed.

(1) Silica-29 NMR

^{29}Si is a $\frac{1}{2}$ spin nucleus with a natural abundance of 4.9%, which is higher than ^{13}C (1.1%). It can be characterized as a magnetically diluted isotope of medium sensitivity (Uhlir and Marsman, 2008). It gives rise to narrow resonance lines, and the full-width at half maximum height (FWHM) is typically < 1 ppm. Because of its important role as a structural framework constituent and its high sensitivity to structural effects, ^{29}Si is one of the most favorable isotopes for structure studies of ceramics and glass-ceramics. However, a broad background signal at ~ 110 ppm and a long relaxation time are common problems of the ^{29}Si experiment. Applying population transfer pulse programs such as DEPT or INEPT can avoid or improve these problems (Uhlir and Marsman, 2008). In crystalline silicates, Si atoms are surrounded by different numbers of bridging oxygens (BO). With decreasing numbers of BO atoms, the silicon nucleus is deshielded and its isotropic chemical shift shifts to a more negative position in NMR spectra. The number of BO atoms can be identified by ^{29}Si NMR and denoted by Q^n (n : numbers of bridging oxygen atoms bonded to Si). The total range of ^{29}Si chemical shifts in silicates is from -60 to -120 ppm. For monosilicates (Q^0), the chemical shift range is -60 to -70 ppm; the chain end group (Q^1) is from -70 to -80 ppm; middle groups in chains (Q^2) is between -80 to -90 ppm; the chain branching sites (Q^3) is around -90 to -100 ppm and the three-dimensional cross-linked framework (Q^4) is around -100 to -110 ppm. ^{29}Si chemical shifts are sensitive to the Si-O bond length, bridging angles and second and third neighbor environments, and so the different chemical shifts can be observed between the chemically equivalent but crystallographically inequivalent Si atoms (Uhlir and Marsman, 2008). Each resonance represents structurally inequivalent Si sites, and quantitative information for the different sites can be determined from normalized peak intensities. Moreover, the local environment of the SiO_4 tetrahedron in the framework can be interpreted by chemical shift change, for example, increasing the degree of SiO_4 polymerization introduces high-field shifts of chemical shift and low-field shifts can be observed when Al is substituted for Si in the second coordination sphere (Lippmaa *et al.*, 1980; Uhlir and Marsman, 2008).

For some binary silicate glasses $M_{(1 \text{ or } 2)}\text{O-SiO}_2$, ($M = M^+$ or M^{2+}) the typical ^{29}Si NMR resonance for Q^4 is around -110 ppm, with FWHM between 7–13 ppm. Introducing each additional NBO results in Q^n to Q^{n-1} conversions, which can be observed by the downfield shifting by between 9 and 12 ppm in the ^{29}Si NMR spectrum (Edén, 2012). Typical ranges of the ^{29}Si chemical shifts for the various $\text{Si}(\text{O})_{4-n}(\text{OSi})_n$ and $\text{Si}(\text{OSi})_{4-m}(\text{OAl})_m$ (m = numbers of bridging oxygen atoms associated with Al) units in glass has been well established (Uhlir and Marsman, 2008). The quantity information of each Q^n species can be acquired by spectral deconvolution, and Gaussian peak shapes are normally applied. In binary silicate glass networks, the relative Q^n populations and BO and NBO species among its tetrahedral structures can be derived from ^{29}Si NMR experiment. Linear relationships between $1/R$ (R = radius of cation) and the ^{29}Si FWHM of each Q^n structure are reported (Murdoch and Stebbins, 1985; Maekawa *et al.*, 1991; Malfait *et al.*, 2007). Intensive studies have been carried out on the BO/NBO effect (Eckert *et al.*, 1989; Szu *et al.*, 1992; Cong *et al.*, 1993; MacKenzie *et al.*, 1994; Sen and Stebbins, 1995; Bhasin *et al.*, 1998; Schneider *et al.*, 2000, 2003; Shrikhande *et al.*, 2001; Takaishi *et al.*, 2005; Malfait *et al.*, 2007). There are two models: (1) a binary distribution model, where two tetrahedral units, Q^n and Q^{n+1} coexist in the network, where the fractional populations $X_n + X_{n+1} = 1$, (2) a random distribution, implying the statistical sharing of the NBO ions among the tetrahedra, for which the mathematical expressions are described by Edén *et al.* (2011). Some research providing high-quality NMR spectra confirms that BO/NBO distribution is close to a binary distribution but with some elements of a random distribution (Dupree *et al.*, 1986; Stebbins, 1987; Grimmer *et al.*, 1988). Because of this randomness in the glass structure, the number of Q^n species is increased. This broadens the distribution of Si-O bond lengths and Si-O-Si bond angles for each species, which causes the loss of NMR spectral resolution (Dupree *et al.*, 1986; Schneider *et al.*, 2000, 2003). Spectral resolution degradation also occurs when the alkaline-earth content is increased, or additional network formers (B or Al) are introduced (Schneider *et al.*, 2000; Schneider *et al.*, 2003). Certain binary silicate glass systems, such as Rb and Cs silicate glasses, have limited ^{29}Si NMR resolution for distinct Si sites. However, the signal can be enhanced by increasing the alkali content up to 50 mol% (Malfait *et al.*, 2007; Dupree *et al.*, 1986).

(2) Phosphorus-31 NMR Spectra

With a moderately large magnetic moment, ^{31}P provides a favorable sensitivity for NMR experiments. It can be used to analyze short-range structures around the nucleus, because of the correlations between anisotropic chemical shift and structural features. From previous studies (Roufosse *et al.*, 1984; Aue *et al.*, 1984; Miquel *et al.*, 1990a,b; Wu *et al.*, 1994; Grossmann *et al.*, 2000; Oliveira *et al.*, 2000; Hartmann *et al.*, 2001; Kolodziejski and Klinowski, 2002; Jaeger *et al.*, 2005; Tseng *et al.*, 2006; Tsai *et al.*, 2008; Marti-Muñoz *et al.*, 2019), it is well known that the values of the ^{31}P chemical shift

anisotropy varies with different Q^n -group structural units in solid phosphates, either crystalline or amorphous. The isotropic chemical shift also correlates with the field strength of the cations around the phosphate anions. Thus, the isotropic chemical shift parameters can be used to investigate the relationship between cations and the PO_4 -tetrahedra (Griffin *et al.*, 1990; Miquel *et al.*, 1990a,b).

There are substantial studies related to ceramic structures being investigated by ^{31}P NMR. Different ^{31}P pulse sequences including proton-decoupled Bloch decay, cross-polarization (CP), and dipolar suppression techniques are employed to study hydroxyapatite and carbonate-hydroxyapatite (Aue *et al.*, 1984). The different pulse sequences alter the contribution of specific types of PO_4 tetrahedra (Roufosse *et al.*, 1984). In ^{31}P CP MAS NMR experiments, the spinning frequency is set to 4.2 kHz. The ^{31}P resonance at 2.9 ppm assigned to PO_4^{3-} groups and two weaker shoulder peaks at 5.4 and 0.8 ppm which were respectively assigned to unprotonated PO_x and protonated PO_x (Aue *et al.*, 1984; Griffin *et al.*, 1990; Miquel *et al.*, 1990a,b; Wu *et al.*, 1994). CP experiments show that it is possible to detect the presence of phosphoproteins in bone at the very earliest stages of bone mineralization. CP experiments also can be used to monitor the formation of an initially amorphous calcium phosphate layer and its subsequent crystallization into hydroxycarbonate apatite, and such a method provides a valuable criterion for the design of osseointegration biomaterials (Wu *et al.*, 1998; Cassella *et al.*, 2000).

Advanced double-resonance NMR experiments combined with X-ray powder diffraction can be used to identify the chemical composition of crystallization intermediates, and to study crystallization mechanisms in glasses (Chan *et al.*, 2001). The Rotational Echo Double Resonance (REDOR) experiment allows quantitative determination of the dipolar coupling. For example, in ^{13}C - $\{^{31}P\}$ REDOR experiment, it makes a quantitative determination of the ^{13}C - ^{31}P distance possible. This is very useful for study of bone tissue since ^{13}C nuclei are very largely found in the organic matrix while ^{31}P spins are very largely confined to the inorganic component. Thus any ^{13}C - ^{31}P distances in the bone structure are relevant to the organic-inorganic interface (Jaeger *et al.*, 2005).

Structural features of silica-phosphate glasses and glass-ceramics have been studied by ^{31}P MAS NMR (Yang *et al.*, 1986; Oliveira *et al.*, 2000; Yan *et al.*, 2001; Chan *et al.*, 2001; Stamboulis *et al.*, 2004; Kharlamova *et al.*, 2008; Tsai *et al.*, 2008; Dietrich *et al.*, 2009; Mason *et al.*, 2009; Brauer *et al.*, 2010; Mneimne *et al.*, 2011; Bradtmüller, 2019). These researchers have found that the introduction of phosphorus in to alkaline-earth silicate glasses increases the degree of polymerization of the silicate network (Yang *et al.*, 1986).

(3) Fluorine-19 NMR Spectra

^{19}F NMR is widely used in many fields because the F nucleus has experimental advantages. It has spin one-half, and fluorine chemical shifts are highly sensitive to the local environment, which is due to an F ion normally surrounded by eight electrons. This full occupation of 2s-2p orbitals yields more information about the fluorine's neighborhood than hydrogen which only has a single electron. This facilitates the study of the structure and dynamics in fluorine compounds.

^{19}F NMR has been extensively used to study fluoride substituted apatite ($Ca_{10}(PO_4)_6(OH/F)_2$) (FHA) (White *et al.*, 1988; Kreinbrink *et al.*, 1990; Cho and Yesinowski, 1996; Rafferty *et al.*, 2004; Mason *et al.*, 2009). It occurs naturally in tooth enamel. In the inorganic apatite component, F ions replace OH^- ions to a level as high as 50 mol% (Mason *et al.*, 2009). In bone, approximately 1 wt% F can be found in the inorganic component. The natural FHA provides low solubility and good acid resistance to the enamel surface. In bone, it helps prevent reductions in bone density. Due to these biological benefits, FHA can be utilized as an implant material for bone and dental restoration. The fluoridation level of FHA is crucial in biomedical applications. This is because the different fluorine contents have major effects on the crystallization, solubility and thermal stability of the bulk apatitic material. The ^{19}F MAS NMR is the most and only reliable technique to detect fluoride substitution in apatite. This is because FHA has a similar crystal lattice to hydroxyapatite. They both belong to the hexagonal crystal system with space group $P6_3/m$. The only difference is that along the c axis, F atoms substitute for OH groups. The ionic radii of the OH^- and F^- are very close, which are 1.68 and 1.32 Å, respectively (Braun and Jana, 1995a). Thus, apart from a contraction of the c -axis in the lattice structure, there are no significant crystallographic dimensional changes. This structural similarity causes a major challenge in determining the fluoridation levels of FHA using Powder X-ray Diffraction (PXRD) solely. Besides, detection of the light elements such as F, O and H is known to be problematic for PXRD. Crystallographic studies of F substituted hydroxyapatite have been carried out previously, it found the (002) peak of FHA is shifted toward the lower angle and (300) peak is shifted toward the higher angle, also (211) and (112) peaks show merging and overlapping to each other (Braun *et al.*, 1995b; Jana and Braun, 1996). That XRD pattern analysis merely proved that the F^- ion incorporation in the c -channel in the apatite structure and the F/OH solid solution formation. Fourier transform infrared spectroscopy (FTIR) has found that F^- substituted OH^- results in the OH^- vibrational mode at 631 cm^{-1} shifting to higher wavenumbers at 747 cm^{-1} depending on the number of OH^- groups in the positions between each F^- position (Freund *et al.*, 1977; Barinov *et al.*, 2004). Other techniques such as Energy Dispersive X-ray Spectroscopy (EDS) and Atom Probe Tomography (APT) can be used to quantify the amount of F in the samples but they fail to distinguish the different chemical environments of F (Mitric *et al.*, 2004; Rodriguez-Lorenzo, *et al.*, 2003; Bachhav *et al.*, 2013). So ^{19}F MAS NMR is one of the few techniques available that can unambiguously qualify and quantify analyses of fluoridated apatite, whether the solid is crystalline or amorphous. In Gao's paper (Gao *et al.*, 2016), a series of FHA with various fluoridation levels from 0% to 200% were studied by PXRD, FTIR, ^{31}P and ^{19}F MAS NMR. A non-linear relation between ^{19}F NMR chemical shift and fluorine substitution level has been found. With increasing F contents, the ^{19}F CS shifts from -104 to -106 ppm. ^{19}F MAS

Fig. 4 ^{27}Al chemical shift range (green represents the coordination number six or higher, orange coordination number five, blue four and purple three). Reproduced with permission from Martineau, C., *et al.*, 2016. The use of ^{27}Al NMR to study aluminum compounds: A survey of the last 25 years. In: Patai's Chemistry of Functional Groups. John Wiley & Sons, Ltd. Copyright (2009–2016), John Wiley & Sons, Ltd.

NMR also can be used to distinguish the level of crystallinity for the environment F^- in of FA. When F⁻ is in a low degree of crystallinity environment, the ^{19}F CS occurs at -103 ppm, while if it is in the high crystallinity environment, the ^{19}F MAS NMR resonance arises at -102 ppm.

Braun and Jana's (1995a) work also found a correlation between ^{19}F chemical shift and the F content in the apatite. In Mason's work (Mason *et al.*, 2009), a second ^{19}F resonance was observed and this corresponded to a second F environment in the apatite structure at a concentration similar to that of B-type carbonate. In 2013, Yi *et al.* (2013) proved that this additional ^{19}F signal corresponds to isolated fluoride ions in the apatite structure, which is close to the substituted carbonate group.

(4) Aluminum-27 NMR Spectra

^{27}Al has 100% natural abundance with a nuclear spin 5/2, making it a quadrupole nucleus. Quadrupolar nuclei ($I > 1/2$) is classified into those with integer spins (1, 3 etc.) and half-integer spins (3/2, 5/2 etc.). For example, deuterium (^2H) and nitrogen (^{14}N) have nuclear spin 1, and ^{10}B has nuclear spin 3; spin 3/2 are ^{17}O and ^{23}Na , 5/2 are ^{25}Mg and ^{27}Al , 7/2 are ^{59}Co and ^{43}Ca , and 9/2 are ^{87}Sr and ^{93}Nb . 75% of NMR active nuclei are quadrupolar (Duer, 2002), and they are dominant in several molecular systems ranging from porous materials, ceramics and glasses, to superconductors and biological systems such as nucleic acids and proteins (Engelhardt, 1989).

Quadrupolar nuclei not only possess a magnetic dipole moment, they also have an electric quadrupole moment. This electric quadrupole moment interacts with the electric field gradient. The size of the electric field gradient is determined by the molecular and electronic structure around the nucleus, or more precisely, it depends on the orientation of the molecule with respect to the applied magnetic field, which is anisotropic. The interaction can be rather large, resulting in powder patterns of megahertz in width for non-cubic symmetric solid samples. Typically, the quadrupolar interactions vary from a few kHz to a few MHz leading up to 2000–3000 MHz in the case of ^{127}I (Martineau *et al.*, 2016). Apart from the line broadening arising from the interaction between the quadrupole moment and the electric field gradient, the complexity in spin dynamics due to the presence of more than two energy levels has also impeded the routine study of quadrupolar nuclei (Tsai *et al.*, 2008). The established spin-1/2 techniques, such as magic-angle-spinning (MAS) and cross polarization (CP), do not always provide isotropic high resolution spectra in quadrupolar systems (Martineau *et al.*, 2016).

^{27}Al is a useful tool for structural characterization of numerous crystalline or amorphous Al-containing ceramics and glasses. ^{27}Al chemical shifts cover a range of resonances from -100 to 300 ppm relative to the chosen reference, $\text{Al}(\text{H}_2\text{O})_6^{3+}$, at 0 ppm (Martineau *et al.*, 2016). The coordination number of aluminum can be revealed by the chemical shift (see Fig. 4). In general, aluminum atoms with lower coordination numbers are at the downfield part of the spectrum. For example Al(III) is in the

Fig. 5 (a) 2D ^{27}Al 3Q MAS NMR spectrum of a mazzite zeolite sample (b) 1D projection of the slices S1 and S2 (c) 1D ^{27}Al MAS NMR of mazzite zeolite sample and the fitting comparison of using Lorentz lines and 3Q MAS NMR spectrum. Reproduced with permission from Pike, K.J., *et al.*, 2000. Multiple-quantum MAS NMR of quadrupolar nuclei. Do five-, seven- and nine-quantum experiments yield higher resolution than the three-quantum experiment. *Solid State Nuclear Magnetic Resonance* 16, 203–215. Copyright (1999), American Chemical Society. Wouters, B.H., *et al.*, 1999. Determination of the $\text{Al}^{\text{T1}}/\text{Al}^{\text{T2}}$ ratio in MAZ zeolites using line shapes of MQ MAS NMR. *Journal of Physical Chemistry B*, 103 (38), 8093–8096.

range between 300 to 250 ppm. With increasing coordination number, the ^{27}Al chemical shift shifts to the up-field which is lower and negative values of δ as shown in detail in Fig. 4. (Martineau *et al.*, 2016).

As ^{27}Al is a quadrupolar nucleus, the NMR pulse program for $1/2$ spins is not necessarily straightforward. Several techniques have been developed to deal with quadrupolar nuclei with a broad central transition such as DAS (dynamic angle spinning), MQMAS (multiple-quantum magic-angle spinning) and STMAS (Satellite transitions magic-angle spinning). More structural information can be obtained from MQMAS NMR spectra, such as the relative distance between the Al nucleus and other nuclei (^{27}Al , ^{29}Si and ^1H) (Edén, 2012).

The high-resolution NMR experiment MQMAS, introduced by Frydman in 1995 (Baltisberger *et al.*, 1996), has greatly extended the use of NMR for half-integer quadrupolar spins. MQMAS is a 2D solid state MAS NMR experiment, which separates quadrupolar from chemical-shift interactions by observing them differently, along with two different directions in the frequency domain. Under MAS conditions, the vertical dimension F1 is the isotropic indirect spectral dimension and the direct horizontal dimension F2 corresponds to the central transition. The projection of the resonance onto the F1 is free from anisotropic line broadening, therefore, the F1 dimension is well resolved. For quadrupolar nuclei with nuclear spin $I > 3/2$, 3QMAS ($-3/2 \rightarrow -3/2$ transition), this is the most used approach. Higher order 5QMAS can offer better signal separation, but at the price of a significant loss of efficiency (Amoureux and Fernandez, 1998; Fernandez and Amoureux, 1995; Wouters *et al.*, 1999).

Zeolites are a unique class of porous solid aluminosilicates. Structural studies of zeolites attracts much attention due to their stability and catalytic activity with high selectivity, which makes them an ideal catalyst materials. ^{27}Al MAS NMR can offer aluminum coordination information. However, it fails to resolve sites with similar environments. ^{27}Al MQMAS provides good resolution for the various ^{27}Al sites and becomes a useful tool for structural characterization of zeolites. Fig. 5 was published by Wouters *et al.* (1999); Pike (2000). They studied a mazzite zeolite with ^{27}Al 3QMAS spectra. There are two crystallographically distinct tetrahedral sites, T1

Fig. 6 (a) ^{27}Al MAS NMR spectrum and deconvolution of Al (IV), Al (V) and Al(VI) for a $4.5\text{SiO}_2\text{-}3\text{Al}_2\text{O}_3\text{-}1.5\text{P}_2\text{O}_5\text{-(}5\text{-z)}\text{CaO-zCaF}_2$ glass and (b) relationship between the fraction of each Al coordination number and fluoride content of the glass. Reproduced with permission from Matsuya, S., *et al.*, 2007. Structural characterization of ionomer glasses by multinuclear solid state MAS NMR spectroscopy. *Journal of Non-Crystalline Solids* 353 (3), 237–243. Copyright (2006), Elsevier B.V.

and T2, into which Al can be incorporated. The $\text{Al}_{\text{T1}}/\text{Al}_{\text{T2}}$ ratio can be determined by Lorentzian line fitting the 1D ^{27}Al MAS NMR. However, two tetrahedral Al lines showed substantial narrowing with increasing magnetic field from 9.4 to 14.1 T (Engelhardt, 1989). This indicated that quadrupolar interactions have an impact on the NMR line shapes. So instead of using Lorentzian-Gaussian line shapes, slices S1 and S2 from MQMAS were used to deconvolute the 1D MAS spectrum (Fig. 5(C)), which not only resulted in the different Al distribution ($\text{T1}/\text{T2}$) also much better fit ($R = 7.6 \times 10^{-3}$).

A bioactive glass based on $\text{Na}_2\text{O-CaO-SiO}_2\text{-P}_2\text{O}_5$ system was developed by Hench in 1971 (Hench and Paschall, 1973). It showed excellent biocompatibility and bone bonding ability. By modifying the glass compositions, the ion release rate, degradation rate and bonding affinity of bioactive glass can be adjusted to facilitate bone tissue engineering (Kirkpatrick and Brow, 1995; Chan *et al.*, 2001; Brauer *et al.*, 2009; Mathew *et al.*, 2011; Pedone *et al.*, 2012). Combining ^{27}Al , ^{19}F , ^{29}Si and ^{31}P MAS NMR is a comprehensive way to characterise the structure of bioactive glasses (Baltisberger *et al.*, 1996; Karpukhina *et al.*, 2007). Matsuya *et al.* (2007) studied $4.5\text{SiO}_2\text{-}3\text{Al}_2\text{O}_3\text{-}1.5\text{P}_2\text{O}_5\text{-(}5\text{-z)}\text{CaO-zCaF}_2$ ($z = 0\text{--}3$) glasses using ^{27}Al , ^{31}P , ^{19}F , and ^{29}Si . Three resonances were de-convoluted from ^{27}Al MAS NMR spectra, including an asymmetric broad peak at 50 ppm, a shoulder peak at 30 ppm and a small peak at -5 ppm (Fig. 6(a)). These corresponded to Al(IV), Al(V) and Al(VI), respectively. Furthermore, on the basis of this

structural analysis, a correlation between Al coordination numbers and F content was discovered (see Fig. 6(b)). It was found that the proportion of Al(IV) decreased linearly with increasing F content. Al(V) increased with fluoride content up to $z = 1$ then became almost constant between $z = 1$ –3. The proportion of Al(VI) increased with increasing fluoride content $z \geq 1$ (Matsuya *et al.*, 2007). This data showed that as fluorine substituted for oxygen in the glass then more aluminum was present in the glass as a modifier {Al(V), Al(VI)}.

Outlook

Thanks to the advancement of hardware and methodology in MAS NMR, significant progress has been achieved on the understanding of the structure of ceramics and glasses. Apart from the ^{29}Si , ^{31}P , ^{19}F , and ^{27}Al MAS NMR, ^{13}C , ^{43}Ca , ^{25}Mg and ^{17}O analyses have also proved to be feasible techniques for structure characterization. However, ^{43}Ca , ^{25}Mg and ^{17}O have low-gamma half integer quadrupole nuclei, and so sensitivity is an issue for the application of MAS NMR to them. Further development of the signal enhancement techniques is required, such as dynamic nuclear polarization (DNP) (Griffin *et al.*, 2010).

X-Ray Powder Diffraction

Introduction

X-Ray diffraction has acted as the cornerstone of twentieth-century science. Its development has catalyzed advances in solid-state science and much of our understanding of chemical bonding. X-Ray powder diffraction (XRPD) plays a critical role in materials research and development because many materials and minerals are not readily available in single-crystal form. Some 10,000–20,000 powder diffractometers are in use worldwide, and more than 1 million reference patterns are available in the International Center for Diffraction Data Powder Diffraction File (PDF) electronic database. Although the technique is termed “powder diffraction”, any polycrystalline specimen may be studied using the technique, including monolithic solids, thin films, and powders (Cullity, 1978; Jenkins and Snyder, 1996; Klug and Alexander, 1974). Among the applications of powder diffraction are:

- (1) Qualitative identification of the phases present in a specimen using the powder pattern as a “fingerprint” of the phase which may be compared to known powder patterns stored in a database.
- (2) Quantitative analysis of the concentrations of each phase present in a multiphase specimen can be carried out.
- (3) The unit cell metrics, i.e., the size and shape of the unit cell, of any crystalline material can be determined, and then refined to very high accuracy. Because the lattice parameters of a material change with chemical composition, XRPD finds widespread use in solid solution analysis, phase diagram work, and for measuring the true density of materials.
- (4) Full orientation distribution functions that describe the crystallite orientation in polycrystalline materials can be determined.
- (5) Residual and applied stress can be determined by measuring the strain present in the crystallites composing a monolithic body.
- (6) Microstructural features of a polycrystalline material including the crystallite size, microstrain within crystallites, and defect densities may be determined.
- (7) In situ techniques under controlled gaseous atmosphere, temperature, pressure, field, and mechanical loading provide a means of determining phase diagrams and reaction kinetics, and provide a means of tracking changes in materials during synthesis and processing.
- (8) Full structure solution from powders (*ab-initio* structure solution).
- (9) Analysis of local versus long-range structure, using the Pair Distribution Function (PDF) method.

The applications listed above are strictly for polycrystalline materials. It is important to note, however, that powder diffractometers may be equipped to study thin films using X-Ray reflectivity and high-resolution diffraction.

Origins of X-Ray Powder Patterns

X-Rays are relatively short wavelength, high-energy electromagnetic radiation. Diffraction experiments require X-Ray wavelengths of the order of the interatomic spacing to produce interference, and hence typical wavelength ranges are 0.07–0.2 nm. The most common radiation used in the laboratory is Cu K_α radiation with $\lambda = 0.15406$ nm.

A typical X-Ray powder diffraction pattern is shown in Fig. 1 and consists of diffraction peaks, or “lines”, as a function of the diffraction angle, 2θ . Diffraction occurs when waves scattering from an object constructively and destructively interfere with each other (Hahn, 1983; Gilmore *et al.*, 2019). The diffraction peaks in Fig. 1 are a result of constructive interference of waves scattered from the atoms or ions composing a crystal. M. von Laue in 1912 first determined that X-Rays diffract from the periodic arrangement of atoms in a crystal, exactly analogous to the diffraction of visible light from a grating. Based on the work of von Laue, both Bragg and Bragg (1913) showed that diffraction from a crystal is described by the equation now known as Bragg’s law:

$$\lambda = 2d_{hkl} \sin\theta \quad (1)$$

This equation allows one to measure the perpendicular distance (d_{hkl}) between imaginary planes which form parallel families and which intersect the repeating unit cell filled with atoms in a way described by the Miller indices (hkl). X-Rays of wavelength λ may be thought of as reflecting from these imaginary planes at the measurable angle θ , where θ is one-half of the diffraction angle as shown in Fig. 1. A powder pattern therefore contains a set of diffraction peaks at 2θ positions that correspond to the interplanar spacings in the crystal. Although d_{hkl} may be calculated using geometry for any set of (hkl) planes in any unit cell, the interplanar spacings are most easily calculated in reciprocal space. Ewald (1913, 1921) developed what is by far the most useful method for describing diffraction phenomena using reciprocal space.

Ewald showed that a reciprocal lattice can be constructed by using the reciprocals of all of the distances in a real unit cell. The reciprocal lattice has the same symmetry as the real crystal lattice, but the points in the reciprocal lattice are equally spaced and hence simple to manipulate. In an orthogonal lattice (cubic, tetragonal, orthorhombic), all distances are the reciprocals of the real space distances. $\mathbf{a}^*$, $\mathbf{b}^*$, and $\mathbf{c}^*$ are the reciprocal lattice parameters, while the interaxial angles are α^* , β^* , and γ^* , where the

Fig. 1 A powder diffraction pattern for a mixture of two phases, with the standard patterns from the PDF database shown below the data.

reciprocal of an angle is defined as the complement or 180° minus the angle. Likewise, the reciprocal of $\mathbf{d}_{hkl}$ is $\mathbf{d}_{hkl}^*$. In the non-orthogonal systems, one must account for the interaxial angles when calculating the reciprocal lattice parameters.

The convenience of using reciprocal space is demonstrated when calculating the $\mathbf{d}_{hkl}^*$ values. Since the length of $\mathbf{d}_{hkl}^*$ is simply related to the real space d -spacing, one simply uses the $\mathbf{d}_{hkl}^{*2}$ equation:

$$\mathbf{d}_{hkl}^{*2} = h^2 \mathbf{a}^{*2} + k^2 \mathbf{b}^{*2} + l^2 \mathbf{c}^{*2} + 2hka^* \mathbf{b}^* \cos \gamma^* + 2hla^* \mathbf{c}^* \cos \beta^* + 2klb^* \mathbf{c}^* \cos \alpha^* \quad (2)$$

This expression relates the square of the inverse of $\mathbf{d}_{hkl}$ to the size and shape of the reciprocal unit cell for any plane in any crystal system. For many applications then, Eq. (2) reduces to a particularly simple form. For example, Eq. (2) becomes:

$$\mathbf{d}_{hkl}^{*2} = (h^2 + k^2 + l^2) \mathbf{a}^{*2} \text{ for a cubic crystal.}$$

The intensity of each diffraction peak in a pattern is governed by the structure of the crystal and the physical configuration of the diffractometer. First we must consider how much intensity a single electron will coherently scatter (the more massive nucleus is a very inefficient scatterer and may be ignored). Next we need to consider the interference effects which will occur due to the electrons being distributed in space around atoms and the fact that atoms are not stationary in a lattice but vibrate in an anisotropic manner. Then the interference effects of atoms scattering from different regions of the unit cell must be allowed for, and finally the optical configuration of the diffractometer and absorption effects must be considered.

The intensity of peak i of phase α in a powder pattern measured using Bragg–Brentano geometry (see Fig. 2) is described by the following equation:

$$I_{ix} = \frac{I_0 \lambda^3 e^4}{32 \pi m_e^2 c^4} \frac{M_i}{2 V_\alpha^2 \mu} |F_{ix}|^2 \frac{[(1 + \cos^2 2\theta_i \cos^2 2\theta_m)]}{[(\sin^2 \theta_i \cos \theta_i)]} \quad (3)$$

where:

$$F_{hkl} = \sum_{j=1}^N \left[(f_{j0} + \Delta f_j' + \Delta f_j'') \exp(-B_j) \times \sin^2(\theta/\lambda)^2 \right] \exp 2\pi i (hx_j + ky_j + lz_j) \quad (4)$$

N = No. of atoms in cell.

The first term in Eq. (3) describes classical scattering from an electron as described by J. J. Thomson in 1899 (Nobel Prize for Physics, 1906), while the last term in parentheses is a correction for the polarization of the X-Ray beam on diffraction. The term M_i accounts for the multiplicity of (hkl) planes with identical d -spacings that diffract at the same angle; for example, there are six $(h00)$ peaks in a cubic crystal. The structure factor, F_{hkl} , is the most important quantity in crystallography and contains the atomic scattering factor, f_j , and the atom positions in the unit cell, x_j , y_j , and z_j . The exponential term in F_{hkl} (Eq. (4)) accounts for the phases of the scattered waves, while the atomic scattering factor accounts for the amplitudes scattered from each atom. f_j

Fig. 2 Schematics of two x-ray powder diffractometers: (a) Bragg-Brentano parafofocusing geometry; (b) parallel beam geometry using a parabolic multilayer optic.

completely describes scattering from an atom by including the number of electrons and their spatial distribution around the atom, including thermal vibrations (B_j). It is important to note that f_j explicitly includes the atomic number of each element in a crystal, demonstrating that X-Rays scatter more strongly from heavy elements than from light ones.

It is a triumph of our understanding of physics that computations of diffraction intensities, using Eq. (3), produce the observed values. This triumph has been heavily exploited in determining the crystal structure of materials. This ability, first used by the Braggs in 1913, has established the basis of modern solid-state science.

The most common application of our ability to compute a powder pattern, in the materials laboratory, is to compare it with any features of the experimental pattern (like preferred orientation of the crystallites, solid solution effects, etc.) to determine any crystal structure or microstructural modifications which may have taken place.

Instrumentation for X-Ray Powder Diffraction

Traditional Parafofocusing Instruments

Beginning in 1945 and continuing through the 1950s, William Parrish developed the powder diffractometer for recording powder patterns electronically (Parrish, 1949). The diffractometer is shown schematically in Fig. 2. The parafofocusing geometry is called Bragg-Brentano but should more appropriately be called Parrish geometry (Bish and Post, 1990). The parafofocusing principle in the diffractometer comes from keeping the X-Ray source (i.e., the X-Ray tube target), the specimen, and the receiving slit on a common circle, called the focusing circle. To meet the condition of Bragg's law we must move the sample through an angle of θ while the detector is scanned through an angle of 2θ . This θ - 2θ motion implies that the radius of the focusing circle is continually changing throughout a diffraction pattern scan.

The need to make the beam monochromatic follows directly from Bragg's law. If more than one wavelength is present in the beam, each set of planes will yield a diffraction peak for each wavelength. This would hopelessly complicate the diffraction pattern. The most common method to produce "monochromatic" radiation is to employ a diffracted-beam monochromator. Most Bragg-Brentano instruments include a quasi single-crystal graphite monochromator which allows only the $K_{\alpha 1}$ and $K_{\alpha 2}$ radiation to reach the detector, as shown in Fig. 2. The elimination of all spectral wavelengths from the X-Ray tube except the $K_{\alpha 1}$ and $K_{\alpha 2}$ greatly improves the quality of the powder pattern. Placing the monochromator in the diffracted beam not only removes spectral impurities from the X-Ray tube but also any fluoresced X-Rays from the specimen.

Although Bragg-Brentano geometry is by far the most common configuration for powder diffraction, the parafofocusing nature of the measurement makes it prone to significant systematic errors. By far the most serious of these is due to a displacement of the

sample from the focusing circle. This, of course, can never be avoided because even if the sample surface is perfectly tangent to the focusing circle, the X-Rays penetrate into the sample to an average depth dependent on the absorption coefficient of the sample. Thus, there is always a “sample displacement” (or “sample transparency”) error present. One can remove these errors to obtain high-accuracy measurements of peak positions by using certified line position standards available from NIST.

Parallel-Beam Diffractometers

Revolutionary new X-Ray optics have been developed that have proved to be effective for laboratory measurements. Multilayer optics, polycapillary optics, and high-performance channel-cut crystals have been used independently or together to build high-intensity and/or high-resolution parallel-beam diffractometers.

A parallel-beam measurement minimizes or completely eliminates systematic errors arising from sample displacement and transparency. In addition, a parallel beam is required for asymmetric diffraction experiments, including thin-film diffraction. A parallel-beam diffractometer, therefore, lends itself to powder and thin-film measurements with little or no systematic errors. The only potential disadvantage of a parallel-beam diffractometer is termed “particle statistics”. Compared to a divergent beam Bragg–Brentano instrument, a parallel-beam instrument will reduce the number of crystalline grains in a powder specimen that are exactly oriented to produce a diffraction peak. One must therefore take special care to ensure that powder specimens are finely ground or polycrystalline samples are rotated or oscillated to increase the number of grains bathed in the X-Ray beam.

Both graded multilayer and polycapillary optics may be used to convert a divergent beam into a parallel beam, or to focus an X-Ray beam. Multilayer optics consist of thin-film stacks of alternating high atomic number materials with low atomic number materials. The alternating thin films therefore act as a crystal, the diffraction angle of which is determined by the thickness of the films and is typically below 3° . Herbert Göbel first showed that by grading the film thickness of each layer along the length of a multilayer optical element and bending it to a parabola or ellipse, either parallel or focusing beams may be produced. This optic is now called a Göbel mirror.

Polycapillary X-Ray optics use hollow capillaries as waveguides for X-Rays, where multiple total external reflection of X-Rays from the smooth inner walls of capillary channels can be used to redirect an X-Ray beam. The curvature of the capillary determines the final direction of the X-Ray beam, and bundles of capillaries may be used to produce parallel or focusing beams.

One optical assembly includes a parabolically curved graded multilayer coupled to channel-cut silicon or germanium crystal monochromators. The multilayer produces a beam with divergence of the order of 100 s of arc, which is then diffracted by the latest generation of two- or four-bounce channel-cut crystals. The result is a high-intensity, highly monochromatic beam that allows extremely high-resolution measurements in the laboratory. In fact, diffraction peak widths as narrow as 0.035° 2θ have been measured, which is commonplace when using a synchrotron source but unheard of for a laboratory instrument.

A schematic of a parallel-beam diffractometer is also shown in Fig. 2 for comparison with the Bragg–Brentano geometry.

Modern X-Ray Detectors

The nature of X-Ray detectors and the electronics used with them is an important part of understanding the approaches to, and limitations of, X-Ray applications. Many modern X-Ray diffractometers employ “point” detectors that collect data through a very fine receiving slit, but one- and two-dimensional detectors are becoming common in powder diffraction, as shown schematically in Fig. 3.

The standard point detectors work using a scintillation crystal to convert X-Ray photons to blue light, which is then converted to an electrical signal using a photoelectric material. Solid-state detectors are another variety of point detector, and convert the incident X-Ray photon directly to an electrical signal by creating electron–hole pairs in a doped semiconductor crystal.

Solid-state and scintillation detectors are both point detectors because there is no means of determining where the photon collides with the detector. In contrast, one- and two-dimensional position-sensitive detectors sense where the X-Ray photons strike the detector and can therefore be used to collect some angular range of data in parallel. Collecting diffraction data in parallel significantly decreases the measurement time, often down to seconds and even microseconds.

Fig. 3 Schematic of detector configurations.

The common one-dimensional position-sensitive detectors (PSDs) cover angular ranges of some 5° – 120° 2θ and work using gas ionization to absorb the photon and a timing signal to detect the arrival of the electrical pulses at a position analyzer.

Two-dimensional detectors include gas proportional designs, charge-coupled devices, or image plates to collect a large area of the cone of diffracted intensity from a powder specimen. Most recently, amorphous Si and CMOS technologies have become commonplace, which have 2-D pixel sizes near $100\ \mu\text{m}$ with excellent dynamic range. 2-D detectors can be used to collect the entire Debye cone of diffracted radiation if the detector is centered on the beam, or some part of the diffracted cone of radiation, with the option of re-positioning the detector during measurement. As of the year 2020, it has become common to employ such solid state 2-D technologies in both 1-D and 2-D detection schemes. For laboratory diffractometers, 2-D detectors are generally as large as 10 cm diameter for gas-filled counters or 5 cm for solid state devices. Data collection times using two-dimensional detectors are often of the order of seconds or less per image.

Applications of Powder Diffraction

Phase Identification by X-Ray Diffraction

The set of diffracted d and I values for any material is as characteristic as a fingerprint is for a human. We must now face the same problem the crime solvers have had to face – an observed set of fingerprints is useless unless you have an extensive collection of reference patterns for comparison. Our problem is even more complex in that unknown materials are commonly composed of more than one phase. When this occurs, the observed pattern contains all the diffraction peaks of each phase present.

Scientists have answered the need for a powder diffraction pattern database by creating an organization called the International Center for Diffraction Data (ICDD), which publishes the Powder Diffraction File (PDF) in annual installments. The powder patterns published in the PDF include experimentally determined patterns from the literature and calculated patterns from crystal structure databases. They are reviewed by editors and published in book and computer formats (e.g., CD-ROM). There are about 160,000 patterns in the file.

An example of phase identification is shown in Fig. 1, which is a pattern for a two-phase mixture. The phases are identified using the PDF entries shown in Fig. 1. A number of manual and computer searching methods have been developed over the years to accomplish phase identification. These methods place an emphasis on the accuracy of the intensities (Hanawalt method) or the d_{hkl} values (Fink method) or on the elements present (alphabetical search). Modern highly automated computer search routines use a combination of chemical information, intensity, and peak position, generally coded into heuristic algorithms, to quickly search the database for possible matches. A modern computer search requires only a few seconds, and will often correctly identify at least two phases in any unknown on the first attempt.

Quantitative Phase Analysis

Quantitative phase analysis by X-Ray powder diffraction dates back to 1925 when Navias at GE quantitatively determined the amount of mullite in fired ceramics, and to 1936 when Clark and Reynolds reported an internal-standard method for mine dust analysis. Alexander and Klug (1948) presented the theoretical background for quantitative analysis based on diffracted intensities. Since then there have been numerous methods developed, based on their basic equations. Methods applicable to a wide range of phases and samples include the method of standard additions (also called the spiking method) the absorption diffraction method, the internal-standard method, and the Rietveld method (described below).

Quantitative analysis using any method is a difficult undertaking. It requires careful calibration of the instrument using carefully prepared standards and will require multiple measurements unless the Rietveld method is used. After the technique and standards have been established, routine analyses may be completed in as little as a few minutes to an hour per sample, depending on the precision desired.

The intensity of a diffraction line i from a phase α in a specimen containing a mixture of phases can be rewritten from Eq. (3) as:

$$I_{iz} = K_{iz} X_{\alpha} / [\rho_{\alpha} (\mu/\rho)_m] \quad (5)$$

where K_{iz} = a set of constants describing the diffracted intensity, including the Thomson equation, polarization, etc., X_{α} = weight fraction of phase α , ρ_{α} = density of phase α , and $(\mu/\rho)_m$ = the mass absorption coefficient of the mixture. $(\mu/\rho)_m$ is calculated using tabulated values of (μ/ρ) for each element as a weighted average.

The fundamental problem in quantitative analysis lies in the $(\mu/\rho)_m$ term in Eq. (5). To solve for the weight fraction of phase α , we must be able to compute $(\mu/\rho)_m$ and this requires knowledge of the weight fractions of each phase. Special techniques are therefore required to eliminate the unknown $(\mu/\rho)_m$ and quantify the phase concentrations.

Application of one of the techniques listed above centers on removing the unknown $(\mu/\rho)_m$ term from the analysis. Consider for example the internal standard quantification method, which is the most general of any of the methods for quantitative phase analysis and is based on elimination of the absorption factor $(\mu/\rho)_m$, by dividing Eq. (5) by itself, giving:

$$I_{iz}/I_{js} = k(X_{\alpha}/X_s) \quad (6)$$

which is linear in the weight fraction of phase α . The subscripts i and j refer to different hkl reflections. k is the slope of the internal standard calibration curve: a plot of I_{iz}/I_{js} versus X_{α}/X_s .

The addition of a known amount, X_s , of an internal standard to a mixture of phases, which may include amorphous material, permits quantitative analysis of each of the components of the mixture by first establishing the values of k for each phase, i.e., the slope of the internal standard plot of $(I_{i\alpha}/I_{js})X_s$ versus X_{α} , from standards of known concentration. Use of a pre-established calibration curve, defining the slope k , permits the weight fraction of any phase α in the original mixture to be computed.

Unit Cell Indexing

Determining the size and shape of the unit cell from a powder pattern of a pure phase is simply a 3-dimensional problem linking the set of observed d-spacings to the unit cell metrics (axial dimensions and interaxial angles, also called the lattice parameters). Indexing a diffraction pattern used to be a formidable problem. Indexing is the procedure used in assigning hkl values to the set of planes which give rise to each diffraction line, or, in other words, determining the lattice parameters that define the unit cell. The problem becomes more difficult as one goes to lower symmetry because the number of unknowns one must determine increases. Nonetheless, computer methods can often be used to determine the lattice parameters of an unknown crystal if, and only if, the patterns are measured very accurately and corrected for systematic errors.

The problem of indexing can then be stated as having to solve the d_{hkl}^* equation for up to six unknown lattice parameters. Solving the d_{hkl}^* equation using experimental data will result in some amount of error, and it is convenient to have a means of quantifying the “goodness of fit” of the experimental data to the unit cell determined by solving the d_{hkl}^* equation. A figure of merit (FOM) is used to determine the goodness of fit. The most common FOM was developed by Smith and Snyder (1979) and is defined as:

$$F_N = \frac{N}{|\Delta 2\theta| N_{\text{poss}}} \quad (7)$$

where N is the number of observed lines used in the calculation, N_{poss} is the number of possible diffraction peaks allowed by the space group out to the 2θ of line N , and $|\Delta 2\theta|$ is the average error between the observed and calculated 2θ values of the first N lines in the pattern. This figure of merit is useful both in evaluating the quality of powder patterns and in establishing the correctness of an indexing. The advantage for indexing is that its value is independent of the crystal system, so a common scale can be applied to all crystal systems. With only one unknown lattice parameter the problem of indexing a cubic powder pattern is always solvable. Lower symmetry crystals are significantly more difficult to index, and three fundamental approaches have been useful. Since the problem gets progressively more difficult numerically as we decrease symmetry, all three approaches employ computers. The three approaches are (1) intelligent algorithms, (2) searches of solution space and (3) searches of index, or (hkl), space.

The intelligent procedures try to determine the lattice parameters by applying known relationships from both geometry and crystallography and even previous experience with indexing problems. Two quite successful methods of this type have been developed by Visser (1969) and Werner (1976).

Search methods do a systematic search of solution space (i.e., look at all possible solutions within some boundaries). There are two types of searching index procedures: those that work in parameter space and those that examine index or hkl space. Some of the search methods make assumptions about the regions of solution space that should be examined while others are exhaustive.

We should pause here to discuss the concept of a solution space. This space for an exhaustive parameter search is envisioned as having up to six dimensions in a plane (corresponding to functions relating to a , b , c , α , β , and γ) and the F_N figure of merit plotted perpendicular to this plane. For cubic problems this means a two-dimensional problem: vary all possible values of a along the x axis with F_N plotted vertically. One needs to use caution, however, because there are a great number of incorrect cells that will almost describe the crystal within reasonable error limits. Each of these “solutions” will correspond to a maximum of F_N in solution space. Our assumption is that the highest maximum in F_N corresponds to the correct unit cell.

An exhaustive indexing procedure working in parameter space examines all possible values of a , b , c , α , β , and γ within some reasonable limits defined by the user. The lattice parameters are divided into small increments and each possible set is used in an attempt to index the unknown pattern. Louër and Louër (1972) established an extremely successful program based on this approach.

Exhaustive procedures using index or hkl space examine all possible combinations of h , k , and l which can be used to index each of the lines in the unknown pattern. Here our solution space is four dimensional for all symmetries: axes in integer units of h , k , and l in a plane with F_N perpendicular to that plane. A very powerful algorithm based on hkl space searching was developed by Taupin (1973).

Before the days of powerful, fast PCs, exhaustive search procedures were only practical in relatively high symmetry systems and in a few exceptional cases. For example, the classic case of a manual orthorhombic indexing was performed by Jacob and Warren (1937) in the determination of the crystal structure of α -uranium. As the symmetry decreases to triclinic, the amount of computation required became impractical. Today, however, monoclinic and triclinic problems are routinely solved on researchers’ desktop workstations.

Refining Accurate Lattice Parameters

Once a powder pattern is indexed we may routinely write from one to six d_{hkl}^* equations with all terms known except the one to six lattice parameters. These equations may be solved simultaneously to give values for the lattice parameters, but these will not be the most precise values (Pecharsky and Zavalij, 2009).

The precise and accurate measurement of lattice parameters, or unit cell dimensions, have been used for various purposes such as: determining thermal expansion coefficients, finding the true density of a material, providing a direct measure of interatomic distances, and studying interstitial and substitutional solid solutions.

In order to obtain accurate lattice parameters, the minimization and elimination of a number of errors is necessary. All sources of error in 2θ affect the accuracy of the lattice parameters, and may be classified into two categories: (1) random errors and (2) systematic errors. Random errors are those made in locating and recording the center of the diffraction peak. These errors vary randomly with the angle 2θ .

Systematic errors are those whose magnitude depends upon the position of the line, that is, upon the angle 2θ . Systematic errors are best eliminated by using an internal standard, which is a material certified by NIST to have well-known diffraction peak locations. With systematic error handled in this manner, the common approach for obtaining the most precise parameters from observed data is to use the method of least squares. Least squares minimizes the differences between the observed d_{hkl} values and d_{hkl} values calculated from the d_{hkl}^2 equation by varying the lattice parameters. This very powerful method will simultaneously produce estimates of the standard deviations of the lattice parameters.

Preferred Orientation

Preferred orientation of crystallites in polycrystalline materials is a vital subject to many materials industries. A number of industrial materials are based on directional physical properties of the crystallites. For example, barium hexaferrite ceramic magnets, used commonly as seals on refrigerator doors, are polycrystalline materials in which only the $(00l)$ crystallite directions have a magnetic moment. Thus, the fabrication and quality control procedures must involve manipulating and measuring the degree of preferred orientation in the ceramic. Extruded wires show a characteristic preferred orientation as do most rolled metals, pressed powders, and thin-film materials. The most common way of evaluating the type and extent of preferred orientation is to measure the pole figure for a particular crystallographic direction. The pole figure is simply the intensity of a particular Bragg diffraction peak plotted as a function of the three-dimensional orientation of the specimen. It is determined on a pole figure diffractometer which is essentially the same as a single-crystal diffractometer, able to rotate the specimen through all orientations while monitoring the diffraction intensity of a specific hkl reflection. The results are displayed as a pole figure which is a two-dimensional stereographic projection.

By collecting several pole figures, a complete orientation distribution function (ODF) can be calculated, which describes the orientation of the crystallites in the coordinates of the specimen geometry. The full ODF is often critical for understanding the variation in properties as a function of direction in monolithic polycrystalline parts.

Crystallite Size

When a well-crystallized powder sample with an average crystallite size of $\approx 10 \mu\text{m}$ diffracts, the diffraction peaks are sharp, symmetrical, and well defined. However, if the specimen contains crystallites that are smaller than $\approx 500 \text{ nm}$, possess large internal microstrains, or have a large density of stacking faults or other defects, the diffraction peaks will be broadened and/or asymmetric.

The simple case of crystallite size peak broadening can be understood by considering the interference of X-Rays scattered from different positions in the crystallite (Snyder *et al.*, 2000). A large crystallite, i.e., larger than a few micrometers, contains some 50,000 successive (hkl) planes and produces a narrow diffraction peak. The diffraction peak is narrow because at angles slightly above and below the Bragg angle, complete destructive interference occurs. A photon scattered from the top (hkl) plane will be exactly out of phase with a photon scattered from an (hkl) plane deep within the crystallite; for example 40,000 planes from the surface, at angles very close to the Bragg angle. However, if the crystallite is smaller than the 40,000 planes used in our example, complete destructive interference will not occur and some diffracted intensity will be observed at angles slightly different from the Bragg angle. Naturally, as the crystallite gets smaller, the destructive interference near the Bragg angle decreases and the diffraction peak becomes wider.

The crystallite size broadening (β_τ) of a peak can usually be related to the crystallite size (τ) via the Scherrer equation:

$$\tau = k\lambda / \beta_\tau \cos\theta \quad (8)$$

The additional broadening in diffraction peaks beyond the inherent peak widths due to instrumental effects can be used to measure crystallite sizes as low as 1.0 nm. However, a second cause of broadening, due to microstress within the crystallites, can complicate the picture.

Whatever the cause of microstress in a crystallite, the effect will cause a distribution of d -values about the normal, unstrained, d_{hkl} value.

The broadening in a peak due to microstress (ϵ) has been shown to be related to the peak width as:

$$\beta_\epsilon = 4\epsilon \tan\theta \quad (9)$$

The fact that microstress-induced diffraction peak broadening follows the tangent of θ while crystallite size broadening follows $1/\cos\theta$ allows us to separate these effects. The most common procedure for accomplishing this was developed by Warren and Averbach (1950). In this method, the Fourier transformation of the diffraction peaks of a broadened sample and a standard

material exhibiting no sample broadening are computed. A deconvolution procedure is then carried out in Fourier space to determine the peak broadening that results from crystallite size and/or microstrain.

A significant amount of research is underway to determine appropriately the microstructural features of a powder or polycrystalline body from powder diffraction data. Most of these approaches involve rather detailed computations of the peak widths as a function of diffraction angle. The angular dependence of the peak width is then used to quantify the crystallite size, microstress, stacking faults, and other atomic-scale defects present in a specimen.

Residual Stress

Stresses in a monolithic body at the macroscale are called a macrostress and the distances within the unit cell will become smaller or larger, depending upon the direction and sense (compressive or tensile) of the residual stress. This will be observed as a shift in the location of the diffraction peaks. Essentially, the individual crystallites in a polycrystalline body act as strain gauges, where the diffraction peak location indicates the strain value at the location of the crystallite that is diffracting. Since most stresses in materials are a result of heat treatment, machining, etc., X-Ray measurements of macrostress are normally referred to as residual stress measurements (Noyan and Cohen, 1987).

Careful measurement of the locations of diffraction peaks with the sample in several orientations (with respect to the beam) directly provides the strain present in the specimen as a function of direction. By using a goniometer that allows the specimen to be rotated in three directions, one can determine a full triaxial strain distribution. Given the diffraction elastic constants, the full second-rank stress tensor may be determined.

Like lattice parameter refinements, residual stress measurements are prone to peak location errors and special care must be taken to ensure instrument alignment. When using a Bragg–Brentano diffractometer, stress measurements are best done using high-angle peaks to minimize systematic errors. Typically, a stress-free powder specimen is measured to confirm the instrument performance.

Parallel beam measurements offer the advantage of reduced systematic peak location errors and allow thin-film and stress depth profiling measurements. Surface and near-surface stresses are important in most technological applications because surfaces and films often define the performance of materials.

Profile Fitting and Rietveld Analysis

The most exciting of the profile fitting developments has been the continuing development of a whole pattern X-Ray refinement method to obtain crystal structure information, begun by Rietveld (1969), who applied it to neutron diffraction data.

Rietveld refinement is conducted by fitting a calculated diffraction pattern to the observed data by adjusting each of the variables that describe the diffraction pattern (Young, 1993; Pecharsky and Zavalij, 2009; Dinnebier and Billinge, 2008). Rietveld computations are relatively intensive, and require minimizing the sum of the weighted, squared differences between observed and calculated intensities at every step in a digital powder pattern. The Rietveld method requires knowledge of the approximate crystal structure of all phases present in the specimen.

The input data to a refinement include the space group, atomic positions, site occupancies, and lattice parameters. This method goes beyond the simple computation of intensities from Eq. (3) by distributing the calculated intensity over the kind of profile found using a particular instrument. Appropriately describing the shape of each peak in an X-Ray pattern remains a challenge, but several successful analytical profile shapes have been developed. Of interest are the Voigt, the pseudo-Voigt, and the split Pearson VII profile functions. The Voigt function is an analytical convolution of a Gaussian and a Lorentzian. It therefore ranges from pure Lorentzian to Gaussian type, depending on the ratio of both half-widths. The pseudo-Voigt conveniently allows the refinement of a mixing parameter determining the fraction of Lorentzian and Gaussian components needed to fit an observed profile. The Pearson VII function also allows for the variation in shape from Lorentzian to Gaussian and can rather easily be split to describe asymmetric X-Ray diffraction peaks.

Another approach for distributing intensity in a profile is called fundamental parameters convolution. Instead of using a mathematical function to approximate the shape of each diffraction peak, the fundamental parameters approach “builds” each diffraction peak by convolution of the X-Ray emission profile with the instrumental and sample contributions to the profile shape. Hence, an accurate peak profile is obtained that explicitly includes all aspects of the experiment and sample; the X-Ray source size, receiving slit width, beam divergence, crystallite size, etc. The development of the fundamental parameters method is now quite mature and it is integrated into various programs for XRD analysis including Rietveld refinement.

In a typical Rietveld refinement, individual scale factors (related to the concentration of each phase) and profile, background, and lattice parameters are varied. In favorable cases, the atomic positions and site occupancies can also be successfully varied to obtain the most correct models of the structures of the phases. Preferred orientation, polarization, and systematic errors may also be modeled.

Fig. 4 includes the results of a completed Rietveld refinement. The observed and calculated patterns are shown, along with the difference pattern and the peak position markers. The refinement in Fig. 4 includes all variables except the atomic positions and thermal parameters, i.e., the background, profile shapes, preferred orientation, sample displacement, and scale factors.

Thus the Rietveld method is used to describe all of the features of the specimen, from the crystal structure to full orientation distribution functions in the case of monolithic polycrystalline specimens. It is the most accurate method available for quantitative analysis and provides estimated uncertainties for each of the refined values.

Fig. 4 Rietveld refinement of a two phase mixture of powders.

Fig. 5 High temperature atmosphere controlled XRD study of vanadium oxide polycrystalline thin films. Reoxidation of VO_2 under reduced oxygen partial pressure is shown.

In Situ Analysis

In situ powder diffraction methods can be used to characterize complex systems under controlled conditions of temperature, atmosphere, pressure, applied electric or magnetic field, mechanical loading, or time. Powder diffraction lends itself well to both basic science and materials processing problems. Crystal structures, phase equilibria, anisotropic thermal expansion tensors, volume change in response to gaseous atmospheres, and reaction kinetics are examples of fundamental studies which are enormously simplified using in situ diffraction. In situ diffraction is quite often the only means to determine structures and phase equilibria in systems that cannot be quenched reliably to ambient conditions; for example, in high-pressure geological studies or peritectic melting systems that crystallize on quenching.

Typical materials science problems can often be investigated using laboratory in situ instruments fitted with furnaces, helium displexes for cooling, and controlled-atmosphere chambers. Generally, in situ measurements involve multiple measurements as a function of an external variable, and position-sensitive 1-D or 2-D detectors that reduce the data collection time are convenient. Reaction kinetics can also be investigated using one- and two-dimensional detectors.

Most high-pressure studies incorporate diamond anvil cells to apply pressures up to several hundred kilobars, often at high temperature, and are typically conducted using synchrotron sources.

An elegant example of an in situ measurement is shown in [Fig. 5](#) where we track the evolution of phases in a polycrystalline thin film as a function of oxygen partial pressure and temperature. [Fig. 5](#) shows the reoxidation of VO_2 through V_6O_{13} to V_2O_5 at sub-ambient oxygen partial pressure. Attempting to get the desired phase assemblage in the thin film using trial and error annealing under controlled oxygen partial pressure would take an extensive effort, but in-situ study requires only a few hours or days instead of weeks.

Structure Solution

Ab initio structure solution from powder diffraction data has become more popular as a result of our abilities to extract intensities from powder patterns (Stout and Jensen, 1989). The integrated intensities from a powder pattern are treated as single-crystal intensities and the traditional single-crystal structure solving and refinement procedures can be employed.

The one-dimensional nature of a powder pattern, however, complicates the extraction of intensities because of overlapping reflections. Several pattern decomposition methods have been developed, including individual profile fitting, the Pawley method, and the LeBail method. The former two methods involve fitting peak profiles with positions that are not constrained by the lattice parameters, while the LeBail method relies on the lattice parameters to constrain the peak positions.

After extracting the intensities for each reflection in a powder pattern, traditional methods such as the Patterson method or direct methods can be used to phase the crystal, and Rietveld refinement is then employed to refine the structure. Structure solution from powders has been quite successful for many inorganic materials with small unit cells, and is an emerging technique for larger organic structures.

More recent advances include the use of simulated annealing methods to solve crystal structures from powder diffraction data and also the use of charge flipping algorithms. For both methods, the unit cell is first indexed, and the structure solution formalisms applied next. Simulated annealing involves, in a simple sense, introducing the correct number of atoms into the unit cell and directing the algorithm to randomly place the atoms in the unit cell until a best fit to the data is found. Of course such an approach is not necessarily successful, so constraints and restraints can be introduced, such as bond length limits, and rigid or semi-rigid bodies can be used instead of atoms or ions. Rigid bodies might be a molecule (in the case of molecular solids) or a coordination polyhedron, for example an SiO_4 tetrahedron in a silicate. The latter are often structural configurations that are commonly found in related solids and the use of rigid bodies is often key to successful structure solution from powder data.

The reader is referred to the literature to study charge flipping and its application in powder diffraction, but it is a method that has been used with great success in both single crystal and powder diffraction despite its theoretical complexity.

Pair Distribution Functions

The PDF method is a recent development in the world of powder diffraction, and is related to the radial distribution function used decades ago to understand amorphous structures. While the XRD experiment describes the overall bulk long-range structure of solids via the diffraction peak locations and intensities, total scattering experiments capture all the scattered intensity which includes diffuse scattering between the diffraction peaks. As described by Egami and Billinge (2012), the total scattering pattern is converted to the reduced structure function which is then Fourier transformed to give the reduced pair distribution function, typically denoted $G(r)$ (see Fig. 6). The PDF is therefore a sum of the set of interatomic distances, r , in real space (because of the preceding Fourier transform) and as such the PDF is of great utility in the study of amorphous and nanocrystalline materials. In fact, even “bulk” crystalline solids with complex chemical makeup may have nanoscale order or disorder that is not described by the diffraction data but is easily captured using PDF analysis.

PDF analysis is best done under experimental conditions that capture a wide range of momentum transfer, or in other words, using short wavelengths and/or wide angular ranges. Large data ranges are needed because the peak widths in the $G(r)$ function sharpen as the data range increases because of the Fourier transform operation. In a laboratory setting, it is common to use Mo or Ag radiation, with wavelengths near 0.71 and 0.56 Å, respectively, instead of the more commonly employed Cu, Fe, or Co sources. While it is feasible to measure PDFs in a laboratory diffractometer, the measurements are time intensive; they may take 5–20 h or

Fig. 6 X-ray pair distribution function for a Au-Cu disordered alloy showing measured, modeled and difference patterns.

even longer. Naturally, the use of synchrotron radiation improves data collection times; purpose-built PDF beamlines today can collect full high-quality PDFs using large area detectors and wavelengths as short as 0.15 Å in <5 min for bulk samples.

Fitting models to measured PDF data is handled as it is in Rietveld analysis, using a model of a unit cell, at least in its simplest form. Naturally, describing amorphous solids or nanoscale disordered materials is not feasible using a traditional unit cell, so modeling approaches employ the use of supercells or even “big-box” models with tens of thousands of atoms. While the topic of modeling complex structures is beyond the scope of this chapter it is worth noting that new approaches are under development for describing more and more complex solids using diffraction and PDF data integrated with advanced computing and statistical methods.

Acknowledgments

This research featured in [Fig. 6](#) used resources of the Advanced Photon Source, a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by Argonne National Laboratory under Contract No. DE-AC02-06CH11357. STM dedicates this chapter to the memory of his mentor and co-author of earlier versions of this chapter, Professor Robert L. Snyder.

Case Studies in the X-ray Diffraction of Ceramics

Maurice Gonon, University of MONS, Mons, Belgium

Introduction

The principle of crystalline phase analysis by X-ray diffraction (XRD) was established by William Lawrence Bragg in the 1920s following Max von Laue's discovery. Since then, XRD has emerged as a powerful tool widely used in research and industry. More specifically, the identification and quantification of the crystalline phases by XRD, at different steps of the process, is a key task of the process control in the ceramic industry. For instance, for traditional silicate ceramics, the characterization the mineral composition of natural raw materials, such as clays, feldspars, talcs, etc, is of major importance as it strongly influences the reactions during sintering, and consequently, the microstructure and properties of the final product (Bonnet and Gaillard, 2007). The crystalline composition also directly affects the mechanical and functional properties of the ceramics. One typical example is given by tetragonal zirconia (TZP) based ceramics in which hydrothermal aging induce a transformation to the monoclinic form that severely degrades strength and toughness (Chevalier *et al.*, 2006; Arata *et al.*, 2014).

However, while XRD is usually well known for qualitative and quantitative analyses of crystalline phases in materials, far more information can be obtained from a careful analysis of the diffraction patterns or by using specific XRD settings. Hence, the characterization of solid solutions (Kima *et al.*, 2013), crystallite size and shape (Popa and Balzar, 2008), preferred crystal orientations (Pentecost and Wright, 1963), internal elastic strains/stresses at different levels (Serbena and Zanotto, 2012), effects of temperature (Diasa *et al.*, 2005), close surface analysis (Angerera and Strobl, 2014; Strasberg *et al.*, 2014) are all possible. The objective of this paper is to show some examples of these advanced applications of XRD in the field of ceramic materials. First, the basics of XRD analysis required to understand these examples will be summarized. Next, two case studies will be developed: (1) the investigation of the anisotropic thermal expansion behavior of cordierite honeycomb substrates, (2) the development of piezoelectric glass ceramics.

Basics of XRD Analysis

Diffraction Conditions and Diffracted Intensity

The XRD technique is based on the interferences between the waves elastically diffused by the periodically ordered atoms of a crystal lattice. X-ray diffraction conditions can be expressed by the Laue condition (Fig. 1). The interferences between the waves elastically diffused by the atomic patterns of the lattice points are constructive if the difference between the diffused wave vector $\vec{k}$ and the incident wave vector $\vec{k}_i$ corresponds to a reciprocal vector $\vec{s}_{(hkl)}$ (1):

$$\vec{k} - \vec{k}_i = \vec{s}_{(hkl)} \quad (1)$$

As $\vec{s}_{(hkl)}$ is normal to planes (hkl) and its length is $1/d_{(hkl)}$, diffraction condition can also be expressed by the Bragg's law (2):

$$\lambda = 2d_{(hkl)} \sin \theta \quad (2)$$

The interplanar distance between (hkl) planes is linked to the unit cell parameters $(a, b, c, \alpha, \beta, \gamma)$ by the relation (3):

$$d_{(hkl)} = \sqrt{\frac{1 - \cos^2 \alpha - \cos^2 \beta - \cos^2 \gamma + 2 \cos \alpha \cos \beta \cos \gamma}{\frac{h^2}{a^2} \sin^2 \alpha + \frac{k^2}{b^2} \sin^2 \beta + \frac{l^2}{c^2} \sin^2 \gamma - \frac{2hk}{bc} (\cos \alpha - \cos \beta \cos \gamma) - \frac{2lh}{ca} (\cos \beta - \cos \gamma \cos \alpha) - \frac{2hk}{ab} (\cos \gamma - \cos \alpha \cos \beta)}} \quad (3)$$

Diffraction conditions are expressed with respect to the lattice points of the crystal lattice. Actually, it is every atom within the crystal unit cell that scatters the X-rays. Consequently, the diffracted intensities are modulated according to the nature and the relative positions of the atoms. It follows that the intensity $I_{(hkl)}$ of the observed diffraction peak when given planes (hkl) meet the diffraction conditions is proportional to the square of the structure factor $F_{(hkl)}$ (4):

$$F_{(hkl)} = \sum_e f_e^x \exp[2\pi j(x_e + \gamma_e + z_e)] \quad (4)$$

- $x_e; y_e; z_e$ are the coordinates of the atoms in the unit cell.
- f_e^x are the scattering factors of these atoms.

The X-ray Diffractometer

Although different kinds of devices can be used for operating X-ray diffraction analyses, the most common equipment is the diffractometer Fig. 2(a). This equipment uses an X-ray tube as radiation source. The most common anticathode is Cu ($k\alpha_1 = 154.056$ pm, $k\alpha_2 = 154.152$ pm) but other sources (e.g., Co, Fe) of shorter or longer wavelengths can be use in specific

Fig. 1 Schematization of Laue and Bragg diffraction conditions.

Fig. 2 Conventional X-ray diffractometer (a) and schematic diagram of the Bragg-Brentano configuration (b).

cases. A scintillator counter is commonly used as X-ray detector. Radiation filtering is operated by means of a thin filter or of a curved monochromator in order to remove the background and undesired spectral lines of the X-ray source but also the fluorescence emissions of the specimen. Divergence angles of incident and diffracted beams are controlled by slits.

A goniometer allows control of the deviation angle 2θ and the incident angle γ with respect to the analyzed surface of the specimen **Fig. 2(b)**. In a conventional configuration (Bragg-Brentano), the incident angle is equal to θ , so that the normal $\vec{n}$ to the surface of the specimen corresponds to the normal $\vec{s}_{(hkl)}$ to the diffracted planes. Consequently, only the planes (hkl) that are parallel to specimen surface can meet the diffraction conditions. When analyzing solid specimens, a possible preferential orientation of the crystals will affect the relative intensities of the diffraction peaks observed on the diffraction pattern and possibly will make some peaks disappear. To avoid this, XRD is usually performed on fine powder milled specimens (powder diffraction method) which normally leads to a random orientation of the crystals. However, one must be vigilant when analyzing a powder exhibiting a particular shape of grains such as wires or platelets (for example raw materials such as kaolin or talc). Indeed, the grains may easily be oriented when preparing specimens for analysis.

Some goniometers use an Euler cradle **Fig. 3(a)** that allows the control of the orientation of the normal to the diffracting planes $\vec{s}_{(hkl)}$ with respect to the normal to specimen surface $\vec{n}$ through the χ and φ angles **Fig. 3(b)**. The application fields of the Euler cradle are the characterization of crystals textures (preferred orientation) and characterization of internal stresses.

Diffraction Peak Shifts and Broadening

According to Bragg's law, for a given crystal structure the diffraction peaks appear at well-defined angles $\theta_{(hkl)}$. Experimentally, a distribution of the intensity $I_{(hkl)}$ is observed around the diffraction angle. In addition, shifts of peaks with respect to expected $\theta_{(hkl)}$ angles are sometime observed.

From the differential of the Bragg law, shifts $d\theta_{(hkl)}$ result of changes in $d_{(hkl)}$ spacing (5)

$$\frac{d(d_{(hkl)})}{d_{(hkl)}} \sim -\cot\theta_{(hkl)} \cdot d\theta_{(hkl)} \quad (5)$$

Note that well defined $d\theta_{(hkl)}$ require homogeneous changes $d(d_{(hkl)})$ over all the diffracting volume.

Among the origins of the changes in $d_{(hkl)}$, we mainly find solid solutions, elastic strains due to internal stresses and lattice thermal expansion in the case of high temperature XRD analyses (HT-XRD).

Fig. 3 X-ray diffractometer with Euler cradle (a) and schematic diagram of the control of the orientation of the diffracting planes with respect to the specimen surface.

The broadness of diffraction peaks is usually characterized through β , the FWHM (Full Width at Half Maximum), and is a function of θ . One part is linked to the configuration of the equipment (β_{inst}), and the other part characterizes the analyzed specimen (β_{sp}) (6):

$$\beta^n = \beta_{inst}^n + \beta_{sp}^n \quad (6)$$

With n between 1 and 2 according to the shape of the peaks (Lorentzian, Gaussian, Pseudo-Voigt,...).

Equipment contribution β_{inst} can be calibrated by determining the Caglioti function (7) from a reference sample (usually LaB_6):

$$\beta_{inst}^2 = W + V \tan \theta + U \tan^2 \theta \quad (7)$$

Considering the differential of the Bragg's law, one possible reason for a peak broadening is a non-homogeneous change $d(d_{(hkl)})$ over all the diffracting volume that leads to a range of $d\theta_{(hkl)}$. The main origins of this are: i). microstrains associated with lattice defects and ii). non-homogeneous solid solutions. The second reason for peak broadening is the limited size T of the crystallites.

The contribution β_{cs} of the crystallite size T for a given (hkl) diffraction peak is obtained by the Scherrer relation (8):

$$\beta_{cs} = \frac{K\lambda}{T \cos \theta_{(hkl)}} \quad (8)$$

K is a constant with a value between 0.8 and 1.2 depending on the peak shape. The value of T corresponds to the size of the crystallites in the normal direction to (hkl) plane. If the crystallite shape is anisotropic, the contribution β_{cs} varies from one (hkl) diffraction peaks to another.

The contribution $\beta_{\mu s}$ of the microstrains is given by the relation (9):

$$\beta_{\mu s} = 4\epsilon_{\mu} \tan \theta_{(hkl)} \quad (9)$$

One way to evaluate the average crystallite size and the microstrains is to use the Williamson-Hall relation (10) which assumes that β_{sp} is the arithmetic sum of the two contributions. Consequently, $\beta_{sp} \cos \theta_{(hkl)}$ becomes a function of $\sin \theta_{(hkl)}$:

$$\beta_{sp} \cos \theta_{(hkl)} = \frac{K\lambda}{T} + 4\epsilon_{\mu} \sin \theta_{(hkl)} \quad (10)$$

The intersection with the Y-axis gives the crystallite size T and the slope gives the microstrains ϵ_{μ} **Fig. 4**.

Penetration Depth of X-rays

The information collected during an XRD analysis comes from a limited depth below the specimen surface. Absorption of X-rays follows the Beer-Lambert law (11):

$$I_{\lambda}(x) = I_{\lambda}^0 \exp(-\mu \cdot x) \quad (11)$$

With μ the linear absorption coefficient of the material.

In the case of a Bragg-Brentano configuration, the intensity $I_{\lambda}(z)$ of the radiation emerging out of the sample after diffraction at a depth z is given by the relation (12):

$$I_{\lambda}(z) = I_{\lambda}^0 \exp\left(-\mu \cdot \frac{2z}{\sin \theta}\right) \quad (12)$$

With I_{λ}^0 the intensity of the incident radiation.

Fig. 4 Determination of crystallite size T and microstrains ϵ_{μ} from the Williamson-Hall relation.

Fig. 5 Contribution of the emerging radiation to diffracted signal in the Bragg-Brentano configuration (a) and in the grazing incidence configuration with $\gamma = 0.5^\circ$ (b).

The contribution $R(z)$ of emerging radiation for depth $> z$ to diffracted signal is given by (13):

$$R(z) = \frac{\int_0^z \exp\left(-\mu \cdot \frac{2z}{\sin\theta}\right)}{\int_0^\infty \exp\left(-\mu \cdot \frac{2z}{\sin\theta}\right)} = \exp\left(-\mu \cdot \frac{2z}{\sin\theta}\right) \quad (13)$$

$R(z)$ strongly depends on the absorption coefficient as it is shown in **Fig. 5(a)** for alumina and zirconia. We also notice on these figures the strong influence of the 2θ angle.

When the analysis requires a low depth penetration of the X-rays, the grazing incidence configuration is used and γ is set to low values ($< 2^\circ$). The intensity $I_\lambda(z)$ of the radiation emerging out of the sample after diffraction at a depth z is given by the relation (14):

$$I_\lambda(z) = I_\lambda^0 \exp\left(-\mu \cdot \left(\frac{z}{\sin\gamma} + \frac{z}{\sin 2\theta - \gamma}\right)\right) \quad (14)$$

Contribution $R(z)$ of emerging radiation for depth $> z$ to diffracted signal is given by (15):

$$R(z) = \frac{\int_0^z \exp\left(-\mu \cdot \left(\frac{z}{\sin\gamma} + \frac{z}{\sin 2\theta - \gamma}\right)\right)}{\int_0^\infty \exp\left(-\mu \cdot \left(\frac{z}{\sin\gamma} + \frac{z}{\sin 2\theta - \gamma}\right)\right)} = \exp\left(-\mu \cdot \left(\frac{z}{\sin\gamma} + \frac{z}{\sin 2\theta - \gamma}\right)\right) \quad (15)$$

$R(z)$ rapidly decreases with depth even for low absorption coefficients as it is shown in **Fig. 5(b)** for alumina and zirconia. Moreover, the analyzed depth is negligibly dependent on the 2θ angle.

The Rietveld Method

The Rietveld method is based on the comparison of a calculated diffraction pattern with an experimental pattern in order to refine the structural and microstructural parameters of the model used for calculation. The intensities observed on the pattern depend on:

- The crystalline phases: crystal structure, microstructure, quantity, cell volume, texture, stress, defects etc;
- The instrument settings: beam intensity, Lorentz-Polarization, background, resolution, aberrations, radiation etc;
- The sample: position, shape and dimensions, orientation.

Refinement aims to minimize the residual function using a non-linear least squares algorithm (16):

$$WSS = \sum_{i=1}^N \frac{(I_i^{exp} - I_i^{calc})^2}{I_i^{exp}} \quad (16)$$

Where I_i^{exp} is the intensity observed on the experimental pattern for the angle $2\theta_i$. The calculated intensity I_i^{calc} for the angle $2\theta_i$ is given by Eq. (17):

$$I_i^{calc} = bkg_i + S \sum_{j=1}^n \frac{f_j}{V_j^2} \sum_{k=1}^p L_{kj} |F_{kj}|^2 T_{kj} (2\theta_i - 2\theta_{kj}) P_{kj} A_j \quad (17)$$

With:

- j , index of the n phases
- k , index of the p diffracting (hkl) planes
- bkg_i , the background
- S , the scale factor
- f_j , the weight fraction of phase j
- V_j , the molar volume of phase j
- L_{kj} , the Lorentz polarization factor
- F_{kj} , the structure factor for diffraction peak k of phase j
- $T_{kj}(2\theta_i - 2\theta_{kj})$, the peak profile function for diffraction peak k of phase j
- $2\theta_{kj}$, the diffraction angle for peak k of phase j
- P_{kj} , the preferential orientation factor for diffraction peak k of phase j
- A_j , the absorption correction factor for phase j

The main information obtained for a given j phase after refinement is:

- The weight fraction f_j ;
- The unit cell parameters from the exact $2\theta_{kj}$ diffraction angles;
- The crystallites size and microstrains from the peak profile $T_{kj}(2\theta_i - 2\theta_{kj})$;
- The preferential orientation from the P_{kj} factor;
- The atom positions and occupation factor from the structure factor F_{kj} ;

Note that for the quantitative evaluation of the phase weight fractions, the microabsorption effects can severely affect the accuracy of the measurements when the phases that are present in the sample exhibit strong differences in absorption coefficients and grain sizes (Pederson *et al.*, 2003). Most of the Rietveld analysis software include correction of microabsorption effects through a coefficient A_j based on different models.

Case Study #1: Investigation of the Anisotropic Thermal Expansion Behavior of Cordierite Honeycomb Substrates

This case study will show how XRD has been used to investigate the anisotropic microstructure of cordierite ($MgO \cdot Al_2O_3 \cdot 5SiO_2$) substrates used as catalyst support for automobile exhaust gas (Callebaut *et al.*, 2007). These substrates present a honeycomb structure composed of channels shaped by extrusion of a green paste Fig. 6.

Ceramic honeycomb structures are widely used as a catalyst support for exhaust gas purification by the three-way catalysis in automobiles and industries, but also as filters or heat exchangers. Among the materials used for producing honeycomb structures, cordierite is a low-cost ceramic that exhibits a high resistance to thermal shock due to its low thermal expansion coefficient.

Cordierite is usually produced by reactive sintering of raw materials as talc, natural and/or calcined kaolin, and alumina. The first part of this work shows the characterization by XRD analyses of the successive phase transformations and reactions that occur with the increasing temperature during the sintering. The second part focuses on investigation of the preferential orientation of the grains of raw materials in the extruded green body, and its consequences on the cordierite crystallites in the fired ceramic. Finally, the third part shows the characterization of the thermal expansion of the cordierite unit cell by High Temperature XRD.

Fig. 6 Green cordierite honeycomb substrate.

Fig. 7 XRD patterns collected on the samples heat treated at 800°C (a), 1050°C (b), 1200°C (c) and 1400°C (d).

Characterization of the Phase Transformations During Reactive Sintering

Samples of the raw materials blend (i.e., talc, natural and calcined kaolin, and alumina) were pressed into pellets and heat treated at 800°C, 1050°C, 1200°C, and 1400°C. X-ray diffraction patterns were collected thanks to a $\theta - \theta$ diffractometer Siemens D5000 (Bragg-Brentano configuration) with CuK_α radiation and graphite monochromator.

The diffraction peaks observed on the XRD pattern of the sample heat treated at 800°C **Fig. 7(a)** correspond to those of the initial talc (JCPDS # 19-0770) and α -alumina (JCPDS # 13-0173). Peaks of kaolinite (JCPDS # 14-0164) are not present due to its transformation into metakaolinite which does not show long range order. This transformation, which leads to the loss of the hydroxyl groups, usually occurs around 500°C:

Fig. 8 Mechanism of formation of cordierite.

The XRD pattern of the sample heat treated at 1050°C does not exhibit the diffraction peaks of the talc anymore Fig. 7(b). Alumina is still present and new peaks are observed. These peaks correspond the protoenstatite $\text{MgO} \cdot \text{SiO}_2$ (JCPDS # 19-0768) resulting from the transformation of the talc according to the reaction:

One can also observe peaks of weak intensities belonging to mullite $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ (JCPDS # 15-0776) formed from the metakaolinite:

The heat treatment at 1200°C leads to the formation of cordierite Fig. 7(c). However, diffraction peaks of alumina, enstatite, and mullite are still present. In addition spinel $\text{MgO} \cdot \text{Al}_2\text{O}_3$ (JCPDS # 21-1150) is evidenced. The cordierite present in the sample at this temperature is the result of the reaction between protoenstatite, mullite, and silica coming from talc and metakaolinite as it is shown in blue in Fig. 8.

Finally, the sample heat treated at 1400°C contains only cordierite as crystalline phase Fig. 7(d). The completion of the transformation is obtained by the reaction between protoenstatite, spinel, and silica coming from talc and metakaolinite as it is shown in green in Fig. 8.

Characterization of Textures in the Green and Fired Bodies

During the synthesis, numerous parameters may influence the apparent expansion coefficient of the final ceramic (Evans *et al.*, 1980). Among these parameters, the size and shape of the raw material particles combined with the shaping process may lead to an orientation of the cordierite crystallites (Lachman *et al.*, 1981; Saha *et al.*, 2001).

The investigated honeycombs are produced by extrusion of the green paste. Green and fired structures were cut and polished to obtain samples corresponding to the sidewall of the honeycomb cells Fig. 9.

XRD analyses were performed on the green and fired honeycomb cells and on the same samples ground into powders. It can be seen on the XRD patterns that the relative intensities of talc and kaolinite peaks do not match with that of the JCPDS files, for both powder and honeycomb cell Fig. 10. Indexing the diffraction peaks with their corresponding Miller indices highlights that for both phases, (00 l) planes exhibit higher intensities, which suggests that (00 l) planes are preferentially oriented parallel to the analyzed surface. Note that this effect is stronger for the honeycomb cell than for the powder.

With the objective of characterizing this orientation, a $\theta - 2\theta$ diffractometer Siemens D5000 with Euler cradle Fig. 3, CuK_α radiation and Fe filter was used to collect pole figures relative to (002) planes of kaolinite and (006) planes of talc. These planes were selected for their high intensities and also for their low convolution with others peaks. The pole figures Fig. 11(a)

Fig. 9 Sample preparation for XRD analysis.

Fig. 10 XRD pattern collected on the green powder (red pattern) and green honeycomb cell (black pattern).

represent, on a stereographic projection, the value of mrd (multiple of random distributions) according to the orientation of the normal to specimen surface $\vec{n}$ with respect to the normal to diffracting planes $\vec{s}_{(hkl)}$ through φ and χ angles **Fig. 3**. In a non-textured sample, $\text{mrd} \approx 1$ for all angles. In the present case the (002) pole figure of kaolinite shows a maximum $\text{mrd} \approx 6$ for $\chi = 0$ and $\varphi = 0$ **Fig. 11(b)**. For the (006) pole figure of talc, the mrd reaches 10 also for $\chi = 0$ and $\varphi = 0$ **Fig. 11(c)**. These results allow it to be concluded that these planes are preferentially oriented parallel to the analyzed surface (the honeycomb cell's sidewalls) and consequently that crystallographic c-axes of kaolinite and talc crystals are preferentially oriented perpendicularly to the direction of extrusion **Fig. 12(a)**. The shape of the platelets of kaolinite crystals and talc combined with the shear stresses generated by the extrusion process can explain this result.

When comparing the XRD patterns of the fired powder and the fired honeycomb cell, it can be seen that the relative intensities of cordierite peaks match with those of the JCPDS file (# 13-0294) for the powder but not for the Honeycomb **Fig. 13**. In order to clearly identify which planes are over or under represented, Rietveld refinement has been performed from data of synthetic cordierite structure (Gibbs, 1966). As expected, the calculated pattern is in good agreement with the experiment in the case of the powder sample **Fig. 14(a)**. On the contrary, strong differences between calculated and experimental relative intensities are observed for the honeycomb cell **Fig. 14(b)**. For this latter, the diffraction peaks corresponding to (hk0) planes are stronger than they should be. This is the case for example for (310) and (020) planes at respectively 17.965° and 18.116° **Fig. 14(c)**.

These analyses pointed out that cordierite crystals grow in a way that the c-axis is perpendicular to the c-axes of talc and kaolinite **Fig. 12(b)**. It must be highlighted that as there is not preferential orientation of the a and b axes of kaolinite and talc, there is no reason for a preferential orientation of the c-axis of cordierite in the sidewall plane.

Characterization of the Thermal Expansion Behavior

HT-XRD patterns were collected on the fired powder using a Bruker D8 Advance instrument (Cu anticathode) with a high temperature chamber. In order to avoid peak shifts due to specimen surface displacement during heating, parallel beam geometry

Fig. 11 Stereographic projection of directions given by angle ϕ and χ (a) and pole figures of (006) talc planes (b) and (002) kaolinite planes (c).

Fig. 12 Preferential orientation of the c-lattice axes of talc and kaolinite grains (a) and of cordierite grains (b).

Fig. 13 XRD patterns collected on the fired powder (black pattern) and fired honeycomb cell (blue pattern).

was realized by a primary Göbel mirror and post-specimen Soller slits. Patterns were collected at RT, 200, 400, 600, 800, and 1000°C on heating (red patterns on Fig. 15 near here) and 900, 700, 500, 300, and 100°C on cooling (blue patterns on Fig. 15 near here).

For most of the diffraction peaks, HT-XRD patterns show shifts to lower angles with increasing temperatures due to lattice thermal expansion (increase in d-spacing). However, these shifts are function of the (*hkl*) planes, and the (002) peak near 19° shifts on the contrary to higher angles. These shifts indicate a strong anisotropic behavior.

Fig. 14 Rietveld refinements of XRD patterns collected on the fired powder (a) and fired honeycomb cell (b)–(c).

Fig. 15 HT-XRD patterns collected on the fired powder (a) and fired honeycomb cell (b).

From the Rietveld refinement of the lattice parameters, the relative variations of these parameters (with reference to room temperature) have been calculated and plotted versus the temperature [Fig. 16](#). Significant differences are observed between the a , b and c lattice axes. The c parameter exhibits almost no change with temperature, unlike a and b . The thermal expansion coefficients (between RT and 1000°C) have been calculated from these graphs: α_c is slightly negative ($-0.7 \times 10^{-6} \text{K}^{-1}$) whereas α_a and α_b are respectively equal to $4.2 \times 10^{-6} \text{K}^{-1}$ and $4.9 \times 10^{-6} \text{K}^{-1}$.

This anisotropic behavior, associated with the preferential orientation of the cordierite crystals, explains the significant differences between the apparent thermal expansion coefficient α measured parallel to extrusion axis ($0.45\text{--}0.55 \times 10^{-6} \text{K}^{-1}$) and the coefficient measured on a non-textured sample of cordierite ($\sim 3 \times 10^{-6} \text{K}^{-1}$).

In addition, the strong anisotropic thermal expansion behavior of cordierite crystals highlights the importance to control the texture of the final microstructure as differences in shrinkage on cooling after sintering may be source of stresses and directly cause cracks in the final parts.

Fig. 16 Relative variations of lattice parameters with temperature.

Case Study #2: Development of Piezoelectric Glass Ceramics

A glass-ceramic is a polycrystalline material obtained by controlled crystallization of a parent glass (Aitken and Beall, 1994). It results in a multiphase material composed of one or several crystalline phases embedded in a residual glass matrix. Properties of the resulting material are mainly given by those of the crystalline phases.

The present case study will highlight the role of X-ray diffraction in the development of piezoelectric glass-ceramics for high temperature applications.

Strontium fresnoite $\text{Sr}_2\text{TiSi}_2\text{O}_8$ is a pyroelectric but non-ferroelectric phase (Schneider *et al.*, 1998). It shows a quadratic symmetry that belongs to the space group $P4bm$, and its lattice parameters are $a = 832.18$ pm and $c = 502.92$ pm. The dipole moment of the unit cell is oriented along the $[001]$ direction.

Its non-ferroelectric behavior is the result of the single domain configuration of the crystals. Consequently, in the case of polycrystalline material, a preferential orientation of the crystallites polar c -direction needs to be induced during the elaboration process to obtain a macroscopically piezoelectric material. This is possible using the glass-ceramics process (Halliyal *et al.*, 1985).

Investigation of the Crystallization of a Glass-Ceramic

The glass-ceramic here presented is obtained by melting, casting and post-crystallizing Fig. 15 a parent glass of composition $2\text{SrO } 1\text{TiO}_2 \text{ } 3.3\text{SiO}_2 \text{ } 0.2\text{K}_2\text{O } 0.1\text{Al}_2\text{O}_3$ (Renoirt *et al.*, 2019) (Fig. 17).

Crystallization treatments performed for various dwell times at temperatures ranging from 850°C to 950°C evidence a surface crystallization mechanism with a crystallization front propagating from the surfaces to the center over time Fig. 18.

After the crystallization treatment, qualitative analyses of the crystalline phases were carried out by XRD with a Siemens D5000 θ - 2θ diffractometer using a CoK_α radiation source. The XRD pattern collected on a powder milled sample after complete crystallization shows fresnoite as the only crystalline phase and a good agreement of the relative intensities with the JCPDS file # 39-0228 Fig. 19(a). Contrarily to the powder specimen, the XRD patterns collected on the glass-ceramic surface exhibit very strong intensities for (001) planes Fig. 19(b), evidencing thereby a preferential orientation of these planes parallel to analyzed surfaces.

Investigation of the Preferential Orientation

In order to follow possible changes in the preferential orientation over depth, XRD analyses were performed at each step of a step-by-step grinding Fig. 20.

Considering a linear absorption coefficient of $0.0316 \mu\text{m}^{-1}$ for the glass-ceramic and a Co K_α radiation, the thickness of the layer of material contributing to the XRD pattern is less than $50 \mu\text{m}$ as it can be seen from the curves R versus z Fig. 21. On that base, the thickness removed at each grinding step between two analyses was set to $100 \mu\text{m}$.

The obtained XRD analyses highlight that the (002) peak intensity decreases in favor of (201) peaks Fig. 22. Pole figures of (002) and (201) planes were also collected after each grinding step. They show a progressive tilt of the (002) planes over the first $300 \mu\text{m}$ Fig. 23. After $300 \mu\text{m}$, (201) planes are parallel to the surfaces and no more changes are observed deeper in the samples.

Investigation of Internal Stresses due to Thermal Expansion Mismatch

The glass-ceramic can be seen as a composite material composed of fresnoite crystals embedded in the residual glass. During the cooling step at the end of the crystallization treatment, the difference in thermal expansion coefficient between the two phases generates homogeneous internal stresses. To evidence this phenomenon, the thermal expansion of the Sr-fresnoite crystals has been characterized by HT-XRD.

Characterization of thermal expansion of the Sr-fresnoite crystals

In order to characterize the thermal expansion of the Sr-fresnoite crystals, a stoichiometric fresnoite parent glass has been melted and crystallized. After milling it into a fine powder, HT-XRD has been performed using a Brucker D8 Advance instrument (Cu anticathode) with a high temperature chamber. Patterns were collected at 30°C; 200°C; 400°C; 600°C; 800°C on heating and 700°C; 500°C; 300°C; 100°C; 30°C on cooling. Variations of lattice parameters *a* and *c* with temperature have been evaluated by

Fig. 26 XRD patterns of the glass-ceramic with 25 wt% (black) and 50 wt% (blue) Ba substitutions (a). Zoom on (002) diffraction peaks (b).

Fig. 27 Evolution of the d-spacing of the (002) planes with the amount of barium.

Rietveld refinement of the patterns [Fig. 24\(a\)](#). The average thermal expansion coefficients α_a and α_c have been calculated [Table 1](#) from the slopes of the curves given the relative variations $\Delta a/a_0$ and $\Delta c/c_0$ as a function of T [Fig. 24\(b\)](#).

Characterization of thermal expansion of the Sr-fresnoite crystals in the glass-ceramic

In a second step, high temperature XRD analyses have been performed on the surface of the glass-ceramic in order to measure the thermal expansion coefficient of the fresnoite crystals constrained in the residual glass matrix. As the fresnoite crystals are strongly preferentially oriented in the glass-ceramic, XRD patterns collected on the surface only exhibit (00 l) planes [Fig. 25\(a\)](#) and only the lattice parameter c can be refined from these patterns. In order to refine the a parameter, HT-HRD patterns were also collected on a cross section of the glass-ceramic [Fig. 25\(b\)](#) on which mainly the (hk0) planes are observed. The maximum temperature was limited at 600°C so as not to exceed the glass transition temperature of the residual glass. Patterns were collected at 30°C; 200°C; 400°C; 600°C on heating and 500°C; 300°C; 100°C; 30°C on cooling.

As for the fresnoite powder, the thermal expansion coefficients α_a and α_c have been calculated from the slopes of the curves given the relative variations $\Delta a/a_0$ and $\Delta c/c_0$ as a function of T. The coefficients obtained are significantly lower than for the fresnoite powder [Table 1](#). The same analyses have been realized on a powder milled glass-ceramic. In this late case, the expansion coefficients are close to that of the fresnoite powder. These results highlight that the fresnoite crystals embedded in the residual glass are not free to expand or shrink normally during a thermal cycle. As the fresnoite expansion coefficients α_a and α_c measured on the solid specimen of glass-ceramic are lower, it can be concluded that the crystals experience tensile stresses during the cooling stage that follows the crystallization treatment.

To verify the validity of this conclusion, the accurate measurement of the fresnoite room temperature unit cell parameters a and c has been realized by Rietveld analysis on 5 samples of glass-ceramic powder and 5 samples of glass-ceramic solids. The parameters calculated for the powder are in agreement with those given by the JCDCS file, whereas those calculated for the solid are slightly higher **Table 2**. This confirms the tensile stresses supported by the fresnoite crystals.

Investigation of the Influence of Barium Substitutions

The effect of substituting strontium with barium on the crystallization of the fresnoite crystals in the glass-ceramic has been investigated. Two new glass-ceramics based on parent glass compositions $1.5\text{SrO } 0.5\text{BaO } 1\text{TiO}_2 \text{ } 3.3\text{SiO}_2 \text{ } 0.2\text{K}_2\text{O } 0.1\text{Al}_2\text{O}_3$ and $1\text{SrO } 1\text{BaO } 1\text{TiO}_2 \text{ } 3.3\text{SiO}_2 \text{ } 0.2\text{K}_2\text{O } 0.1\text{Al}_2\text{O}_3$ have been prepared in the same conditions than for the one without substitution. **Fig. 26** shows the XRD patterns obtained on these two glass-ceramics and the diffraction peaks position for Ba-fresnoite (JCPDS # file 22-0513) and Sr-fresnoite (JCPDS file # 39-0228). These diffraction patterns highlight that the crystalline phases obtained corresponds to fresnoite with a strong (00 l) preferential orientation and that the peak positions are between those of Ba-fresnoite and Sr-fresnoite. These shifts are explained by the largest radius of the barium cations by comparison to the strontium cations. The barium substitution leads to an enlargement of the fresnoite unit cell, and consequently, an increase in the planes d-spacing. Checking of the actual substitution rates is possible by applying Vegard's law. This law considers that the lattice parameters of a solid solution of two constituents are approximately a weighted mean of the two constituents' lattice parameters at the same temperature. In the present case, the application of the Vegard's law to the d-spacing of the (002) planes confirms the expected substitution rates **Fig. 27**.

Conclusion

The objective of this paper was to highlight the potential of use of XRD in the field of the ceramic materials. Two works, for which XRD was the key analysis tool, have been developed. If some of the characterizations performed have require specific equipment that are usually only encountered in research laboratories, one must keep in mind that numerous information can however be extracted from conventional X-ray patterns collected from a basic equipment commonly used in industry for process control. Now for many years, the Rietveld method has been increasingly recognized as essential for the in-depth analysis of the X-ray patterns. A large number of Rietveld software are available, and they integrate more and more features. Finally, technical progresses have also been realized on the hardware. Modern diffractometers provide diffraction patterns showing weak instrumental broadening while keeping short acquisition time.

Preface

This chapter on transmission electron microscopy (TEM) is dedicated to serve the unfamiliar reader as a brief introduction to this exciting and versatile characterization technique, which literally allows the scientist to “take a look” into the complex nature of materials. Since imaging is conducted via electrons that are transmitted through a very thin slice of the material of the order of 1/10,000th of a human hair, details in the interior of the sample can be studied with very high magnifications of up to 25,000,000x. Therefore, we invite you to this hopefully easy-accessible introduction to TEM and its various applications for the investigation of materials on the micro- and nanoscopic scale. Note that in addition to this chapter, two other contributions shed light on the exciting TEM techniques of high-resolution scanning TEM (HR-STEM) and automated diffraction tomography (ADT).

Introduction and Brief History

Transmission electron microscopy (TEM) is a diverse characterization method for solid samples of various materials with a high local resolution capacity. A high-energy electron beam is transmitted through a very thin specimen. This allows the detection of structural features and details in the respective material not only on the surface, but also within the specimen volume. In order to examine structures with a small spatial dimension, the wavelength of the radiation source has to be smaller than the structure itself. With the short wavelength of accelerated electrons, it is possible to achieve a resolving power of 1.0 Ångström (10^{-10} m) or even lower in current state-of-the-art TEM instruments. In combination with the possibility of conducting chemical analysis with similarly high lateral resolution, TEM has become an important characterization tool for many scientific research areas. The possibility of resolving structures down to the atomic level is not only a great achievement for material sciences and nanotechnological applications, but also for other research fields such as for example geoscience, mineralogy and life sciences.

In general, the three main parameters crucial for obtaining a good microscopic image are contrast, magnification and resolution. In microscopy, the resolution limit is defined by the minimum distance two structural features need to maintain, in order to be perceived as two individual objects. The resolution limit is directly coupled to the wavelength λ of the light source. In 1873 Ernst Karl Abbe described this relationship for optical light microscopy:

$$d_{\min} = \frac{\lambda}{n * \sin(\alpha)} = \frac{\lambda}{NA} \quad (1)$$

NA describes the numerical aperture, which is defined as $n * \sin(\alpha)$. Here, n is the refractive index of the immersion medium between objective and object and α stands for the half aperture or objective opening angle. This correlation between wavelength and resolution is also valid for electron microscopy, including scanning electron microscopy (SEM) and TEM. As the resolving power of a light microscope is restricted by the wavelength of the visible spectrum (380–750 nm), the search for other radiation sources became of interest. With the discovery of the electron, Sir Joseph John Thomson laid the foundation for subsequent research in this area in 1897. In the early 1920s, Louis de Broglie introduced the concept of the wave-particle duality and postulated the wave nature of electrons. In consequence, the idea of using electrons as the light source in a microscope gained more and more attention. Since electrons are charged particles, they can be manipulated with electromagnetic fields. This allowed for the development of electromagnetic lenses, which fulfill the same function as optical lenses in a light microscope. In the early 1930s, Max Knoll and Ernst Ruska developed and built the first TEM at the University of Berlin. It took some effort until their TEM reached a resolving power significantly better than any light microscope. The TEM they built in 1933 had three lenses, a magnification of 12,000x and a resolving power of 50 nm. A “few years later” in 1986 Ernst Ruska gained the Nobel Prize in Physics for his achievements; sadly, Max Knoll had already died. The first commercial TEM was built by Siemens in 1939. While the basic components of the TEM have not changed, successive improvement in lens quality, as well as stabilization of high voltage currents was achieved. Also, a better theoretical understanding of electron optics led to the development of special correctors to minimize the effect of lens aberrations (see the section on “Resolution and Lens Aberrations” below). Overall, significant improvements in design and performance are realized in modern TEM instruments.

With an electron wavelength in the range of 0.0037–0.00087 nm, approximately six orders of magnitude smaller than for visible light, the currently routinely available resolution of a TEM lies in the Ångström range. Here, the relativistic electron wavelength depends on the acceleration voltage, which is generated in the electron gun:

$$\lambda = \frac{h}{\left[2m_0eE \left(1 + \frac{eE}{2m_0c^2}\right)\right]^{1/2}} \quad (2)$$

The potential difference (acceleration voltage) is described by E , while h is the Planck's constant, m_0 and e are the electron rest mass and electron charge, respectively, and m_0c^2 is the rest energy. For a non-relativistic consideration, the wavelength can be estimated with following formula: $\lambda = 1.22/(E)^{1/2}$. Even though the scattering and diffraction half angle α is smaller for electrons than for visible light, the significantly shorter wavelength of the electrons compensates for this disadvantage by far (see Eq. (1)), which results in the small d_{min} values achieved with modern electron microscopes.

During the electron beam irradiation and the resulting electron-specimen interaction, a variety of signals is generated. Besides the main signal arising from elastically scattered electrons, Auger electrons, secondary and backscattered electrons, X-rays or inelastically scattered electrons are also created. TEM machines are therefore often equipped with additional detectors for e.g., energy-dispersive X-ray spectroscopy (EDS) or electron energy-loss spectroscopy (EELS), which allow a detailed chemical analysis combined with the high spatial resolution of the microscope. However, these analytical techniques are not covered in this chapter on the basics of TEM; for more information, we refer to the corresponding literature, as for example: Goldstein *et al.*, 1986; Echlin *et al.*, 1986; Flegler *et al.*, 1993; Reed, 2005; Goldstein *et al.*, 2017; Brydson, 2001; Egerton, 2011, 2016.

Sample preparation

With respect to TEM sample preparation, many different techniques and preparation routes exist, which are adapted to the vast variety of investigated materials, their specific properties as well as to the requirements of the individual studies and research questions. Although the procedures significantly differ from each other, one goal is always identical: to prepare a sample that is electron transparent. In order to allow electrons to be transmitted through the sample, the required thickness is commonly of the order of 20 nm to 100 nm. Furthermore, there are certain techniques, such as high-resolution TEM (HRTEM) or EELS, which require especially thin TEM foils.

In this chapter, the main focus is laid upon the preparation of solid non-metallic materials, for example ceramics or glasses, where standard methods such as mechanical grinding and polishing with subsequent ion thinning can be deployed. While these well-established procedures are preferable for hard non-metallic inorganics, other materials benefit from different preparation techniques. Metals are often electrochemically etched (Petzow, 1999); thus no mechanical stress is applied in this method, preventing undesired artefacts from shear forces in the rather soft metals. Very soft materials, like biological samples, are even more sensitive and require other techniques such as ultramicrotomy. Here, upon fixation of the sample in a resin, thin slices are cut from the sample with a sharp steel or diamond knife, which are already thin enough to facilitate electron transparency.

Besides material specific requirements on the preparation method, two main approaches can be distinguished in general: the preparation of (1) powder versus (2) solid or bulk samples. For powder samples, e.g., ceramic powders or nanoparticles of sufficiently small grain size, the preparation via drop coating is comparably simple and fast. The powder is mixed with an appropriate solvent, such as ethanol or acetone, and dispersed in an ultrasonic bath. Subsequently, one droplet of the suspension is placed onto a special TEM grid with a carrier film.

For solid ceramic samples, the preparation is significantly more laborious. First, a sufficiently small piece needs to be cut from the sample material. Ideally, the sample consists of a 3 mm disc, which is compatible with the standardized geometry of TEM grids and sample holders. Subsequently, one side of the sample is ground and polished to form an even surface, ideally without any scratches which would typically result in inhomogeneous ion-milling. A variety of tools exists ranging from simple handheld disc grinders to sophisticated polishing machines. SiC, Al₂O₃, B₄C, SiO₂ or diamond are typically used as abrasive materials. The last polishing steps are usually conducted with lapping paper or abrasive pastes of very small grain sizes less than 1 μ m, in order to obtain high quality surfaces. After completion, the second side of the sample is ground plane-parallel and polished as well, down to a remaining sample thickness of approximately 10–20 μ m. The thin section needs to be mounted onto a TEM grid for support. Grids of different geometries (holes, slots, square or hexagonal meshes) and materials (Cu, Mo, Ni, Au, etc.) are available in order to meet the demands of the individual sample and anticipated TEM investigation.

Besides the described plane-parallel polishing, the so-called dimple grinder is another well-established method for TEM sample preparation. After regular polishing of the first side of the sample disc, an indentation is ground into the middle of the second side. This is done via a fast-turning dimpling wheel with abrasive paste, placed on the likewise rotating sample piece. The process is stopped when the sample center reaches the desired minimum thickness of 10–20 μ m. The outer rim is usually left with a sufficient thickness ($\sim$ 100 μ m) to ensure a self-supporting sample. Dimple grinding is therefore a well-suited method when grids and mounting glue need to be avoided, as is the case for in-situ heating experiments.

Subsequent to polishing or dimple grinding, Ar⁺-ion milling is used to achieve electron transparency by creating one or several small holes in the sample ($\sim$ 10–100 μ m in diameter). At the edge of the hole the sample is typically thin enough to enable the transmission of electrons. In the ion mill, the sample is exposed to a stream of Ar⁺-ions, which are accelerated towards the sample by applying voltages of 0.5 kV to 8 kV (see Fig. 1). The Ar⁺-ions successively remove sample material from the surface, eventually leading to a perforation of the sample. Besides the acceleration voltage, the incident angle of the Ar⁺-ion beam is an important parameter. The larger the angle, the more effectively material is abraded. However, at an angle of approximately 18° and higher, incorporation of Ar⁺-ions becomes the predominant effect. Furthermore, the thickness of the amorphized layer on the sample surface strongly increases. Therefore, an optimum milling angle exists, which is typically in the range of 6°–14°. During thinning, the sample is usually rotated to assure homogenous erosion. Optional cooling with liquid N₂ can be used to avoid heat damage and reduce amorphization. Ion milling with low incident angles and low acceleration voltages can also be applied to remove the

Fig. 1 Schematic illustrating the Ar^+ -ion thinning process. The sample is rotated while Ar^+ -ions bombard the top and the bottom side of the sample. Small volume fractions of the sample are continuously removed until a small hole is generated in the center, being electron transparent at its rim.

Fig. 2 Optical micrographs of thinned TEM samples; (a) an Ar^+ -ion milled dimpled sample, (b) an ion milled plane-parallel thin section with numerous perforations and (c) a wedge-shaped sample prepared via tripod polishing.

residual amorphous layer from the surface. Since non-conductive TEM samples suffer from charging under the electron beam, a carbon coating is applied subsequent to the ion-milling procedure.

If more complex sample geometries need to be investigated with TEM, like multilayer systems or surface coatings, a more target-oriented sample preparation is required. Cross-section techniques exist, where the sample is sliced perpendicular to the desired interface and then glued on the grid in a sandwich-like manner. For the preparation of wedge-shaped samples, *tripod polishing* machines are valuable devices. In this case, after the first side of the sample is polished, the second side is ground down under a low angle of $< 1^\circ$, resulting in a thin electron transparent wedge. If the wedge is very thin, refraction fringes parallel to the edge can be observed under a light microscope which help to control the grinding process. As an advantage of the wedge-shaped sample, Ar^+ -ion thinning can be omitted or reduced to a minimum. **Fig. 2** reveals a comparison of three TEM samples prepared via different routes.

If a specific region within the sample, such as an intrinsic precipitation or a local defect has to be studied in detail, the *focused ion beam* (FIB) technique allows the extraction of TEM foils from the sample with a high spatial resolution. The FIB acts as a normal SEM and utilizes Ga^+ -ions to precisely cut a thin lamella out of the sample, which already has the desired thickness below 100 nm. The lamella is typically in the order of $5\ \mu\text{m} \times 5\ \mu\text{m}$ and needs to be mounted onto a special TEM grid for support and handled via a specific lift-out technique.

A variety of different TEM *sample holders* exist, such as double-tilt holders for tilting the specimen to desired directions and zone axes, heating and cooling holders for in-situ temperature experiments, electrical stages for in-situ E-field experiments or nanoindenters to locally strain the sample. It should also be mentioned that certain sample holders, e.g., for advanced heating in combination with E-field in-situ experiments, essentially depend on FIB preparation.

Components of a TEM Instrument

The setup of a TEM comprises three main parts. The gun as electron source is located at the top, followed by the column, which includes the condenser, objective, intermediate and projector lens systems. At the bottom, the viewing screen is located with a

Fig. 3 Image of a TEM instrument depicting the main components, which are the gun, condenser, objective, intermediate and projective lens system, the sample stage and the viewing screen.

camera chamber or a charge-coupled device (CCD) camera below (Fig. 3). In many ways, the general setup of a TEM instrument is similar to a normal light microscope (LM) viewed upside down. However, while the LM uses visible light, an electron beam is utilized in the TEM. Therefore, the entire column is always kept under high vacuum of $\sim 10^{-5}$ Pa to avoid scattering of the electrons upon collision with gas molecules. This high vacuum in turn requires the sample to be inserted into the TEM via an airlock.

In contrast to a LM, where glass lenses are used, electromagnetic lenses are applied in the TEM to control the electron beam. The magnification can be tuned by changing the current of the respective lenses. Due to the similarities regarding the beam path through the instrument, both types of microscopes have a multi-step image formation in common, which includes the generation of intermediate images and diffraction patterns. An important and unique feature of the TEM is the ability to choose between the two with the intermediate lens system and, hence, to switch between image and diffraction mode (real versus reciprocal space). Considering the upper part of a TEM with the electron gun and the condenser lens system, this setup strongly resembles that of a SEM. However, in the TEM, there is an additional objective lens and further intermediate and projector lens systems below it. While the magnification is changed by simply defining smaller or larger scan areas in the SEM, the projector lens system of the TEM allows adjustment to the desired magnification.

The gun generates and accelerates the electron beam with voltages typically between 100 kV and 300 kV. Thereby, the electrons are released by either thermionic or field emission. In case of thermionic emission, the electrons are emitted via resistance heating of the cathode material, which is commonly a tungsten filament or a LaB₆ single crystal. The emitted electrons pass a Wehnelt cylinder, where they experience a negative voltage (Wehnelt bias) and are converged in a gun cross-over to pass through a hole in the anode plate. The Wehnelt bias controls the electron current and coherence of the electrons to achieve optimal brightness. Best conditions are usually obtained when the cathode emission is in a slightly undersaturated state. A field emission gun (FEG) releases electrons by the application of a high electric field to a cathode with a fine needle-shaped tungsten tip. Their higher emission current density and brightness as well as the lower energy spread renders FEGs superior to guns with thermionic emission. Hence, the majority of modern TEMs relies on this type of beam generation. FEGs can be further distinguished as Schottky type FEGs, with the cathode being coated with ZrO₂ and heated to around 1800 K, and “cold” FEGs, where emission happens at room temperature. The cold FEG has an even higher brightness and a better energy resolution as compared to the Schottky emitter. However, the total current of a cold emission FEG is typically limited to only a few nA, which is adverse for applications where a high current is of advantage. Furthermore, cold field emission requires sequential flashing to clean the emitter surface from contamination due to residual hydrocarbon molecules in the microscope column. Otherwise, this contamination would strongly impede the emission of electrons.

Fig. 4 Schematic depicting the cross-section of an electromagnetic lens built up of a rotational symmetric copper coil, in which the polepieces, made of a soft-magnetic material, are placed. The electron beam passes through the hole in the polepieces, where an electromagnetic field is generated when a current is applied to the copper coil.

The electromagnetic lenses that control the electron beam are built up of rotationally symmetric copper coils, in which the *polepieces* are placed. They are made of a soft magnetic material like iron. The electron beam passes through a hole in the polepiece, where an electromagnetic field is generated as soon as a current is applied to the copper coil (Fig. 4).

The electromagnetic field is axially symmetric and by changing its strength, the refractive power of the lens can be adjusted. When the electrons enter the electromagnetic field, they are affected by the *Lorentz force* $\vec{F} = -e * (\vec{v} \times \vec{B})$, where $\vec{F}$ runs perpendicular to the velocity vector $\vec{v}$ and the magnetic field vector $\vec{B}$. Due to radial field components normal to the optic axis and longitudinal components parallel to the axis, the electrons are forced on a spiral way around the center axis through the lens by the Lorentz force. This also means that the generated image is rotated with respect to the specimen. The degree of rotation changes with magnification; however, in modern instruments this image rotation is compensated for.

The Lens Systems

The first lens system that the electrons pass on their way down from the gun is the *condenser lens system*. Mostly, TEMs comprise two condenser lenses called C1 and C2, where C1 is used to control the spot size (probe) of the focused electron beam. A weakly excited C1 lens results in a large probe (assigned to a small spot size number), while a strongly excited lens causes a small probe. C2 allows either focusing the beam on the specimen for local chemical analysis and convergent beam electron diffraction (CBED) studies, or opening the beam to form parallel beam conditions for conventional and high-resolution imaging or selected area electron diffraction (SAED). The condenser aperture limits the number of electrons reaching the specimen, allowing for adjustment of the beam intensity to which the sample is exposed. It also controls the convergence semi-angle α . For high-resolution imaging especially, a smaller condenser aperture (smaller α) can be used to remove high angle electrons from the beam, which reduces the adverse influence of lens aberrations.

Further down the column, the condenser lens system is followed by the *objective lens*, which is often termed the “heart” of the microscope. Here, the images and diffraction patterns are formed from electrons passing through the sample. The objective lens is often split into two polepieces with the upper one called the condenser-objective lens (C3). The image quality of the TEM is strongly influenced by the electron optics inside the objective lens. The sample sits right inside the lens between the upper and the lower polepiece. In this way it is ensured that the sample is surrounded by a homogenous electromagnetic field, which strongly benefits the image quality. Furthermore, placing the specimen inside the objective lens is crucial for achieving a high magnification. The *magnification* M in a microscope, no matter if it is constructed with electromagnetic or glass lenses, is defined as $M = v/u$, where v is the image distance (from the center of the lens to the image plane) and u is the object distance (from the specimen to the center of the lens). It follows that a high magnification is best achieved by making u very small instead of v larger, which would also imply a longer and more instable column. By placing the specimen within the objective lens, the distance u is reduced to a minimum and high magnifications can easily be achieved. The downside of this setup is the restriction of the sample holder dimensions to fit into the small gap between the upper and lower polepiece. In addition, the objective aperture is mounted between the specimen and the lower objective lens polepiece. Electrons passing the sample are scattered under varying angles. Depending on its diameter, the aperture restricts the angular spread of electrons entering the lower lens, since beams scattered above a certain angle β (collection semi-angle) are stopped by the aperture; hence, only electrons scattered by an angle $\leq \beta$ contribute to the image forming process.

Below the objective lens, an *intermediate lens* system is installed, which allows the operation of the TEM in two different modes: (1) imaging and (2) diffraction mode. It either selects the back focal plane of the objective lens, where the first diffraction pattern is generated, or the image plane of the objective lens, where the first intermediate image is formed, projecting the selected plane on

Fig. 5 Schematic illustrating the two possible modes: diffraction (left) and imaging mode (right). The selection is done by changing the lens current (diffraction strength) of the intermediate lens focusing on either the plane where the first diffraction pattern or where the first intermediate image is formed.

the viewing screen. Thus, it is possible to gain complementary information from real space (image mode) and reciprocal space (diffraction mode), which is a unique feature of the TEM. The schematic drawing in Fig. 5 displays the ray path for both modes.

The area which contributes to the diffraction pattern can be limited by the selected area electron diffraction (SAED) aperture. This aperture is inserted between the objective and intermediate lens system in the height of the 1st intermediate image plane, creating a smaller virtual aperture above the specimen plane. Only electrons passing the SAED aperture contribute to the diffraction pattern monitored.

The *projector lens system* in the lower part of the TEM column is a multi-lens system. It controls the final magnification of the image, which is displayed on the viewing screen. Furthermore, deflection coils are installed along the TEM column, enabling control of the beam tilt and shift, which becomes important for the general alignment of the instrument and for dark-field imaging techniques (see also the section on “Image Contrast in TEM” below).

If suitably equipped, a TEM can also be operated in *scanning TEM (STEM)* mode. Here, certain scan coils are required that allow the incident beam to scan over a small sample region instead of being stationary. The beam is focused to a fine spot and scans the sample while it is always kept parallel to the optical axis. Below the sample, a detector collects the information from the transmitted beam. Commonly, bright-field (BF) and annular dark-field (ADF) detectors are employed, which are differentiated by their acceptance angle. Low acceptance angles mandatorily including the primary beam are characteristic for BF detectors, while ADF or HAADF (high angle ADF) detectors collect only electrons scattered at higher angles. A detailed introduction to STEM can be found in a separate chapter of this Encyclopedia.

Resolution and Lens Aberrations

The resolution of an optical system is defined as the minimum distance between two objects, which can be imaged separately, for example neighboring atoms in a crystal lattice. As shown in the introductory part, the theoretical resolution, assuming ideal lenses and stability, only depends on the wavelength of the light source λ , the refractive index n of the medium, which is 1 for vacuum in the microscope column, and the convergence semi-angle α of the magnifying lens. By convention, α is often denoted as the collection semi-angle β in the context of electron microscopy. Therefore, it is possible to improve the resolution of the instrument by using either shorter wavelengths or increasing β . However, in reality, i.e., for non-ideal electromagnetic lenses, the resolution of the microscope is mainly limited by *lens aberrations*.

Due to mechanical imperfections, lenses and their corresponding electromagnetic fields are never perfectly rotational symmetric. If two perpendicular wave planes, the sagittal and meridional wave pass a lens, they exhibit different focal lengths Δf_A , depending on the deviation from the ideal symmetry. This effect is termed *astigmatism*, causing differences in the otherwise equal defocus settings of the transmitted beams from one single object of the image. Therefore, a point image is transformed into a small ellipse with the length r_A at the focus crossover according to:

$$r_A = \Delta f_A \beta \quad (3)$$

A correction of the astigmatism is possible by the application of stigmators, which are small octupoles that introduce a compensating field to eliminate the respective lens inhomogeneities.

Apart from astigmatism, there are two other main lens aberrations, which are the spherical and the chromatic aberration. Since the magnetic field inside a rotational symmetric lens is not perfectly homogeneous, distal rays of electrons passing the outer rim of the lens experience a stronger magnetic field than those traveling close to the optical axis. In consequence, outer rays are more strongly deflected than inner rays. As a result, a point is imaged in the Gaussian image plane as a small disc with radius r_s , depending on the *spherical aberration* coefficient C_s and the collection semi-angle β of the electromagnetic lens, according to the relationship:

$$r_s = C_s \beta^3 \quad (4)$$

The electron beam in the TEM is generated by a thermionic or a field emission source with a beam energy E_0 , including a narrow intrinsic energy spread. Due to instabilities in the high-tension (HT) supply, inelastic electron-electron and beam-specimen interactions, the ideal energy distribution E_0 is further broadened by a small amount ΔE . Electrons with different energies are refracted differently by the magnetic field of the lens, which leads to the so-called *chromatic aberration* (different colors have different wavelengths and hence different energies). In this case, a point source is imaged as a small disc with radius r_c , depending on the chromatic aberration coefficient C_c , the energy spread $\frac{\Delta E}{E_0}$ and the angle β :

$$r_c = C_c \frac{\Delta E}{E_0} \beta \quad (5)$$

If the spherical and the chromatic aberration are compared with respect to their importance for practical TEM work, the spherical aberration is significantly more relevant in most cases due to its β^3 dependence. However, since real and with that non-ideal samples are investigated, electrons will always experience some energy loss when transmitted through the material. Nevertheless, for thin samples < 100 nm and a HT range of 100–300 kV, the chromatic aberration can in principle be neglected.

Whenever a ray path in an optical or electron optical system is limited by the edge of a lens or by an aperture, the outer rim of the limiting object produces the *diffraction error*, projecting a local point source as a so-called Airy disc in the image (Rayleigh criterion). The smallest distance between two such incoherent point sources, which can still be recognized by the human eye, is defined as the overlap of the intensity minimum of the first with the intensity maximum of the second disc, resulting in the resolution r_{th} of the corresponding electromagnetic lens, which is also termed the *theoretical resolution*:

$$r_{th} = 0.61 \frac{\lambda}{\beta} \quad (6)$$

As shown, the effect of all aberrations depend on β , the collection semi-angle. However, it is not possible to infinitely reduce their effect by using arbitrarily small angles of β , since the diffraction error, with its inverse $\frac{1}{\beta}$ dependency, has the opposite effect. While the lens astigmatism can be corrected and the chromatic aberration is usually neglected in a first approximation, an optimal value for β being the best compromise between the spherical lens aberration r_s and the diffraction error r_{th} , can be calculated by:

$$\beta_{opt} = 0.77 \frac{\lambda^{1/4}}{C_s^{1/4}} \quad (7)$$

$$\text{Inserting } \beta_{opt} \text{ into equation } r(\beta) = (r_s^2 + r_{th}^2)^{1/2} \rightarrow r(\beta) = \sqrt{\left(0.61 \frac{\lambda}{\beta}\right)^2 + (C_s \beta^3)^2}, \quad (8)$$

which can be used to calculate the minimal resolvable distance or best possible resolution achievable in the TEM:

$$r_{min} = 0.91 (C_s \lambda^3)^{1/4} \quad (9)$$

The *resolution limit* r_{min} of a standard transmission electron microscope lies typically around 0.25–0.3 nm; see also Goodhew *et al.*, 2000; De Graef, 2003; Williams and Carter, 2009; Thomas and Gemming, 2013 and Kumar, 2014 as reference. Since the resolution depends on the electron wavelength and hence on the acceleration voltage, TEM instruments with very high acceleration voltages were developed in the late 1980s, in order to achieve an even higher resolution, such as the atomic resolution microscope (ARM) at the Max-Planck-Institute in Stuttgart. With an operating voltage of 1250 kV, this instrument was able to resolve 0.1 nm.

It is interesting to note that shortly after the development of the first commercial TEMs, the search for *aberration correctors* already started in the late 1940s (Scherzer, 1947). Otto Scherzer, who was a faculty member of the physics department at the TH Darmstadt at that time, developed first concepts for C_s correction, which was later further pursued by Harald Rose. In the 1990s, Harald Rose, together with Max Haider and Knut Urban, built the first C_s -corrected TEM instrument (Rose, 1990; Haider *et al.*, 1998; Erni, 2015). In such a C_s -corrected TEM, multipole non-rotational symmetric lenses are combined to generate a negative C_s value, canceling out the existing positive C_s value of the condenser or the objective lens system. More recent developments address the design of correctors for the chromatic aberration. Nowadays, state-of-the-art TEM machines are equipped with combined C_s/C_c correctors, reaching a resolution down to 0.05 nm.

Image Contrast in TEM

Elastic Scattering

In the TEM, image contrast is primarily generated by electron diffraction and scattering events, which occur when the incident electron beam interacts with the specimen. Contrast formation by absorption of electrons plays only a subordinate role. Elastic scattering describes the interaction of an electron with the electric field, *Coulomb interaction*, without altering the momentum of the interacting electron (McLaren, 1991; Williams and Carter, 2009; Pennycook and Nellist, 2011). Coherent scattering occurs under a scattering angle θ smaller than 10° , while an interaction with the positively charged atomic nucleus results in larger scattering angles and incoherent elastic scattering of the electrons; *Rutherford scattering*. The probability that a certain scattering event occurs, is described by the respective scattering cross-section σ . The unit for the cross-section is "Barn". In nuclear physics, 1 b (Barn) = $10^{-28} \text{ m}^2 = 10^{-4} \text{ pm}^2$ is commonly used, while in atomic physics the dimension of 1 Mb = $10^{-4} \text{ nm}^2 = 100 \text{ pm}^2$ is preferred. The cross-section expresses the likelihood that the incident electron initiates a scattering event. The *differential cross-section* $\frac{d\sigma(\theta)}{d\Omega}$ describes the angular distribution of electron scattering at a single atom. The electron is scattered through θ into the solid angle Ω . The differential cross-section can be expressed by:

$$\frac{d\sigma(\theta)}{d\Omega} = \left(\frac{1}{4\pi\epsilon_0} * \frac{Ze^2}{4E_0} \right)^2 * \frac{1}{\sin^4 \frac{\theta}{2}} \quad (10)$$

where Z is the atomic number, ϵ_0 the dielectric constant, e the elementary charge and E_0 the primary electron energy. The scattering intensity of electrons is related to the *atomic form factor* $f_{el}(\theta)$ (or atomic scattering factor), which is a measure of the amplitude of an electron wave scattered by a single atom. Both the atomic form factor and the differential cross-section describe the dependence of the scattering intensity from the scattering angle θ and are related to each other by:

$$\frac{d\sigma(\theta)}{d\Omega} = |f_{el}(\theta)|^2 \quad (11)$$

The atomic form or scattering factor $f_{el}(\theta)$ and the probability σ for elastic scattering to occur decreases with increasing scattering angle θ . Since $f_{el}(\theta)$ depends on the atomic number Z , it implies that the atomic form factor increases with higher atomic number, as illustrated in Fig. 6.

The atomic form factor for electrons can be expressed as:

$$f_{el}(\theta) = \frac{m_0 e^2}{2h^2} \left(\frac{\lambda}{\sin\theta} \right)^2 * (Z - f_X(\theta)) \quad (12)$$

with h as the Planck's constant, m_0 the electron mass, λ the corresponding wavelength and f_X the atomic form factor for X-rays. The first term describes Rutherford scattering from the nucleus of the atom, while the second term correlates to scattering events from the electron cloud. For X-rays, the respective atomic form factor can be expressed as:

$$f_X(\theta) = \frac{-e^2}{mc^2} \int \rho(r) e^{(-2\pi i K \cdot r)} dr \quad (13)$$

where ρ is the electron charge density, K the scattering vector in reciprocal space, with K being $|K| = \frac{2\sin\theta}{\lambda}$ and r the distance between electron and atom core. Note that electrons interact 10^6 – 10^7 times more strongly with the sample as compared to X-rays,

Fig. 6 Atomic scattering factors of different metals as a function of $(\sin\theta)/\lambda$. Redrawn after Hirsch et al., 1965 and McLaren, 1991.

since X-rays only interact with the electron cloud. The stronger interaction of the electron has the advantage that diffracted electron beams have a rather high intensity; however, dynamical effects such as multiple scattering have to be taken into account (see also the sections on "Volume Scattering" and "Bend Contours and Thickness Fringes").

Another parameter that describes the average distance between elastic collisions in a sample is the *mean free path* for elastic scattering Λ_{el} :

$$\Lambda_{el} = \frac{A}{N_A \rho \sigma} \quad (14)$$

where A is the atomic weight, N_A the Avogadro constant, ρ the electron charge density and σ the cross-section. Hence, the lighter the element in the specimen, the larger is the mean free path and less scattering events will occur, thereby lowering the contrast of the TEM image. Note that samples composed of heavy elements have a low mean free path and therefore need to be considerably thinner (sample preparation), as compared to light-weight materials such as for example boron suboxide, B_2O_3 or boron carbide, B_4C .

Volume Scattering

In the section on "Elastic Scattering" above it was shown how scattering occurs at a single atom within the unit cell, taking the atomic scattering factor $f_{el}(\theta)$ into account. When scattering from the entire unit cell of a crystal is of interest, the contribution from all atoms within the unit cell needs to be included and summed. Their relative position to the origin of the unit cell is expressed by the lattice vector r . The resulting phase difference attributed to each atom is described as $2\pi(K * r)$. The intensity of a diffracted beam from a unit cell is then related to the summation over the entire cell, giving the *structure factor* $F(\theta)$:

$$F(\theta) = \sum_j f_j(\theta) e^{-2\pi i(K * r_j)} \quad \text{or} \quad F_g = \sum_j f_j(\theta) e^{-2\pi i(g * r_j)} \quad (15)$$

The scattering vector K can be replaced by the reciprocal lattice vector g , if only the value of $F(\theta)$ at a specific reciprocal lattice point is of interest. The term $g * r$ then equals $(h * x_j + k * y_j + l * z_j)$. For $g * r = N$ with N being an integer, constructive interference results and diffracted intensity is visible. From the structure factor it can be deduced that the *scattering potential* $P(r)$ of the crystal, resulting from the interaction of electron beam and specimen, can be expressed as:

$$P(r) = \frac{h^2}{2\pi m_0 e V_c} \sum_n F_g e^{-2\pi i(g * r_n)} \quad (16)$$

where h is the Planck's constant, m_0 the rest mass, V_c the volume of the unit cell and r_n is the distance between the origin of the crystal and the n^{th} unit cell. The *extinction distance* ξ_g plays an important role on the image contrast formation, as it is closely related to the structure factor via the expression:

$$\xi_g = \frac{\pi V_c \cos \theta}{\lambda F_g} \quad (17)$$

Note that ξ_g represents the characteristic length of a reciprocal lattice vector g . It is related to the lattice parameter via V_c , the atomic number through F_g and the respective energy applied via the wavelength λ . The amplitude ϕ_g of a diffracted beam from a certain specimen volume arises from the summation of the scattering contribution over each unit cell. It is given by the following equation, where F_g is the scattering amplitude of the n^{th} unit cell and r_n defines its origin:

$$\phi_g = \sum_n F_g e^{-2\pi i(K * r_n)} \quad (18)$$

When the *excitation error* s is taken into account, the equation can be rewritten, since $g * r_n$ is always an integer and therefore $e^{-2\pi i(g * r_n)}$ equals 1. With $e^{-2\pi i(g+s) * r_n} = e^{-2\pi i(g * r_n)} * e^{-2\pi i(s * r_n)}$, it follows that:

$$\phi_g = \sum_n F_g e^{-2\pi i(g+s) * r_n} = \sum_n F_g e^{-2\pi i(s * r_n)} \quad (19)$$

The lattice vector r_n can be expressed as $r_n = (xa + yb + zc)$ and the excitation error as $s = (ua^* + vb^* + wc^*)$. It can be assumed that the transmitted volume of the specimen holds a large number of unit cells. The equation for the amplitude ϕ_g of the illuminated volume of the specimen can then be rearranged as a triple integral, including the unit cell volume V_c and $n_x * n_y * n_z$ with $A = n_x * a$:

$$\phi_g = \frac{F_g}{V_c} \int_0^A \int_0^B \int_0^C e^{-2\pi i(ux + vy + wz)} dx dy dz \quad (20)$$

Solving the integrals gives following expression:

$$|\phi_g| = \frac{F_g}{V_c} * \frac{(\sin \pi A u)}{(\pi u)} * \frac{(\sin \pi B v)}{(\pi v)} * \frac{(\sin \pi C w)}{(\pi w)} \quad (21)$$

with u , v and w being the components of the excitation error s along x , y and z . Since TEM samples are typically very thin foils with a thickness of approximately 20–100 nm, while the other two in-plane directions can be considered as infinite from the viewpoint of a traveling electron, the parts describing the x - and y -direction can be set to 1 and hence can be omitted. The intensity of the

Fig. 7 Schematic showing the intensity distribution along u for $v = w = 0$. The full width half maximum (FWHM) $\Delta u \sim 1/A$ is indicated (with $A = n_x \cdot a$). Redrawn after Hirsch *et al.*, 1965.

diffracted beam is related to a $\sin^2$ -function, as illustrated in Fig. 7. The intensity equals the square of the absolute amplitude of the diffracted beam $I = |\phi_g|^2$.

For thin TEM samples, the intensity of a diffracted beam is then described by a sinusoidal function, controlled by the thickness t and the excitation error s , where both variables are perpendicular to g and the surface of the crystal (recall $\frac{\pi V_c \cos \theta}{\lambda F_g} = \xi_g$ being the extinction distance):

$$I_g(s, t) = \left(\frac{\lambda F_g t}{V_c \cos \theta} \right)^2 * \frac{\sin^2 \pi t s}{(\pi s)^2} \quad (22)$$

The scattering and diffraction events described above are considered under the *kinematic theory of diffraction*, where the intensity of the diffracted beam is described under the assumption that only a single scattering event occurs when the electron passes through the TEM sample. This may hold true for very thin TEM foils and in this case, the intensity of the diffracted beam is proportional to the square of the absolute value of the structure factor: $I_g \propto |F_g|^2$. Although most contrast variations in TEM can qualitatively be described by the kinematic theory, in reality however, the kinematic assumption is often insufficient. It does not take the interaction of the diffracted wave with the crystal lattice into account, whereas multiple scattering events are considered in the *dynamical theory of diffraction*. In this case, the intensity distribution of the diffracted waves around reciprocal lattice peaks is described by *dispersion surfaces*, taking extinction and interference effects into consideration, as well as the shape and width of the diffraction peaks. For example, why kinematically forbidden reflections are sometimes observed in diffraction patterns of thicker sample regions can be explained with the dynamical theory. Under these conditions, dynamical effects have to be accounted for and Eq. (22) can be reformulated, leading to the Howie-Whelan equations ("Pendellösung"), as given in Eqs. (23) and (24) in the section on "Bend Contours and Thickness Fringes" below, including the effective excitation error $s_{\text{eff}} = \sqrt{s^2 + \frac{1}{\xi_g^2}}$ instead of s .

Amplitude Contrast

Since the electron wave of the incident beam can change both its amplitude and its phase while it is transmitted through the specimen, two basic image-formation mechanisms can be distinguished: *amplitude contrast* and *phase contrast*.

Amplitude contrast dominates the image formation process for low to intermediate magnifications up to approximately 150,000x, while phase contrast is responsible for the contrast formation at higher magnifications and in HRTEM imaging in particular. Amplitude contrast can be further divided into two principle types: *mass-thickness contrast* and *diffraction contrast* with the latter being most important when analyzing crystalline samples. Mass-thickness contrast is the main mechanism generating image contrast, when the specimen is amorphous. The scattering intensity depends on the atomic number Z (compare Eq. (10)), but also on the thickness of the sample, since when the sample thickness exceeds the mean free path (Eq. (14)), more scattering events will occur.

In order to generate an image from mass-thickness contrast, it is crucial to use the objective aperture, which sits in the back focal plane of the objective lens. While weakly scattered electrons travel close to the optical axis of the lens, more strongly scattered electrons exhibit a larger scattering angle θ . By choosing a certain aperture size, electrons with a larger scattering angle are blocked by the aperture and are, therefore, excluded from the image forming process, which in turn increases the observed contrast.

If the sample is a single- or polycrystalline material, *diffraction* becomes the crucial contrast forming mechanism. When a crystal is orientated in a way that the angle between the lattice planes and the incident electron beam fulfills Bragg's Law, $2d \sin \theta = n\lambda$, constructive interference occurs. If the respective diffraction angle is larger than the semi-angle of collection, a diffracted beam cannot pass the objective aperture and is blocked out. Then, crystals or crystalline areas that fulfill the Bragg condition appear dark, because their diffracted beams are excluded from the image formation process. Therefore, in addition to the objective aperture size, the diffraction contrast always depends on the orientation of the sample. If the sample is tilted, lattice planes which were in Bragg

Fig. 8 TEM bright-field images showing one crystallite in a β - Si_3N_4 ceramic observed in two different orientations; (a) oriented along the [001] zone axis, while in (b) the crystallite is tilted about 3° out of the zone axis (compare also the corresponding diffraction patterns as insets in the upper left corners). The resulting contrast is rather different in both BF-images (orientation contrast). While in (a) the central grain appears dark (Bragg condition), in (b) it shows a similar contrast as the surrounding Si_3N_4 crystallites.

Fig. 9 Imaging techniques employing amplitude contrast by selecting the direct (incident) or one diffracted beam; (a) bright-field (BF) imaging using the direct beam, (b) dark-field (DF) imaging using one off-axis diffracted beam and (c) on-axis dark-field imaging, where the incident beam is tilted to shift the diffracted beam onto the optic axis to minimize the effect of lens aberrations.

condition are rotated out of it, changing the observed image contrast, as illustrated in [Fig. 8](#), where a β - Si_3N_4 grain reveals a different contrast, depending on its respective on-axis versus off-axis orientation. This also serves as a helpful tool, easily allowing a distinction between diffraction and mass-thickness contrast, since the latter does not change significantly when the sample is tilted.

By positioning the objective aperture, located in the back-focal plane of the objective lens, one can choose whether a diffracted or a non-diffracted (the direct or primary) beam is included in the image formation process. In *bright-field (BF) imaging* ([Fig. 9\(a\)](#)), the aperture selects the direct beam and may also select further diffracted beams, depending on the chosen aperture size. A smaller aperture excludes more diffracted beams and hence increases the image contrast.

In contrast to BF, *dark-field (DF) imaging* typically selects only one diffracted beam which is allowed to pass the objective aperture, while the incident beam is blocked out. In this case, only the specifically chosen diffracted beam forms the image. This imaging mode can be further distinguished in *off-axis* and *on-axis DF*. In off-axis DF, the direct beam is kept on the optical axis and the objective aperture is simply moved to the desired diffracted beam ([Fig. 9\(b\)](#)). However, choosing a diffracted beam traveling away from the optical axis, which implies a larger collection semi-angle β , enhances the contribution of the spherical lens aberration $r_s = C_s \beta^3$. Deploying on-axis DF by tilting the desired diffracted beam onto the optical axis avoids this disadvantage ([Fig. 9\(c\)](#)). In [Fig. 10](#), an example for bright- and dark-field imaging is given. Here, thin lamellae of braunite, $\text{Mn}_7\text{SiO}_{12}$, are embedded in a bixbyite $(\text{Mn,Fe})_2\text{O}_3$ single crystal, running along the (100) planes of the host crystal. The corresponding SAED

patterns are shown as insets and the diffraction spots utilized for BF- and DF-imaging mode are indicated (circle in inset). Note that this bixbyite crystal also contains secondary inclusions of nanosized jacobite crystallites, $(\text{Mn,Fe})_3\text{O}_4$.

Bend Contours and Thickness Fringes

Some of the most common contrast variations observed in TEM imaging are due to the usually uneven surface and inhomogeneous thickness of the TEM foil, which results in the so-called *bend contours* and *thickness fringes*. Furthermore, contrast can be generated by imperfections in the sample (crystal defects) such as stacking faults, dislocations, or local precipitations.

Diffraction contrast strongly depends on the orientation of the crystal lattice planes with respect to the incident electron beam. Deviations from this orientation immediately cause a variation in diffraction contrast. If a TEM foil is bent, the crystal structure is deformed and hence the orientation of the lattice planes is changed in consequence. Therefore, only some areas of the bent foil can be exactly aligned in Bragg condition simultaneously, while other areas necessarily are out of Bragg condition. When the diffracted beams are then blocked by a small objective aperture, the corresponding in-Bragg areas are seen as dark lines (**Fig. 11**), while the others remain bright. Because the TEM foil is typically bent in two directions (dome-like structure), the contours appear as areas of contrast, which are bent and curved as well.

Thickness variations of the TEM sample produce the so-called *thickness fringes*. These alternating bright and dark lines are typically observed at the edge of the sample, where it thins out into a wedge shape. Note that ion milling can cause thickness variations of the TEM foil, leading to the appearance of thickness fringes. They also occur, when phase and grain boundaries are inclined with respect to the incident electron beam, which can be explained with the help of the *Howie-Whelan equations* (Hirsch *et al.*, 1965). The change in amplitude of the direct beam ϕ_0 and one strong diffracted beam ϕ_g (two-beam case) passing through a thin slice with thickness d_z of the specimen, can be expressed by two differential equations, which are coupled with each other:

Fig. 10 TEM bright-field and dark-field images of one bixbyite $(\text{Mn,Fe})_2\text{O}_3$ single crystal with braunite $\text{Mn}_7\text{SiO}_{12}$ lamellae. (a) BF of the bixbyite host crystal, (b) DF of braunite lamellae running along the (100) planes of bixbyite. The insets show the corresponding SAED patterns with the respective diffraction spots used for the BF and DF mode. Note that the bixbyite crystal also contains additional inclusions of jacobite $(\text{Mn,Fe})_3\text{O}_4$ labeled as Jac.

Fig. 11 (a) TEM bright-field image revealing dark contrast lines, so-called bend contours, originating from the buckled nature of the thin TEM sample (aluminum foil). (b) Schematic showing the scattering event from a bent crystal; (b) redrawn after Williams and Carter, 2009.

Fig. 12 Schematic of thickness fringes; (a) for two-beam condition ($s = 0$), the intensities of the direct and diffracted beam oscillate in a complementary way (s is fixed and t varies), (b) for a wedge specimen, the fringe separation is determined by the wedge angle and the extinction distance ξ_g , (c) Bright-field TEM image showing thickness fringes marked by arrows in small MgO crystallites; (a) and (b) redrawn after Williams and Carter, 2009.

$$\frac{d\phi_g}{dz} = \frac{\pi i}{\xi_g} \phi_0 e^{-2\pi i s z} + \frac{\pi i}{\xi_0} \phi_g \quad \text{and} \quad \frac{d\phi_0}{dz} = \frac{\pi i}{\xi_0} \phi_0 + \frac{\pi i}{\xi_g} \phi_g e^{2\pi i s z} \quad (23)$$

where z is the height of the TEM sample in beam direction, s is the excitation error and ξ_g the extinction distance. The two equations show that the intensity of the direct and the diffracted beam is coupled and oscillates with changing z -height, which corresponds to the local specimen thickness t . Maxima of the direct beam intensity correlate with minima of the diffracted beam and vice versa, as illustrated in Fig. 12.

The equation describing the intensity of the Bragg diffracted beam I_g is given by:

$$I_g = |\phi_g|^2 = \left(\frac{\pi t}{\xi_g}\right)^2 * \frac{\sin^2(\pi t s_{eff})}{(\pi t s_{eff})^2} \quad \text{with} \quad s_{eff} = \sqrt{s^2 + \frac{1}{\xi_g^2}} \quad (24)$$

where ξ_g is the extinction distance with $\xi_g = \frac{\pi V_{cos\theta}}{\lambda F_g}$ (see Eq. (17) in the above section on "Volume Scattering"), s_{eff} is the effective excitation error and t the thickness of the TEM foil. When the observed crystal in the TEM sample is well aligned, with $s = 0 \rightarrow s_{eff} = \frac{1}{\xi_g}$, the intensity of the diffracted beam (and complimentary to the direct beam) depends on changes in the thickness t , being the origin of the thickness fringes. However, if the sample has a constant thickness but is tilted or the TEM foil is strongly bent, the excitation error s or the effective excitation error s_{eff} strongly influence the observed image intensity.

Contrast of Crystal Defects

While the idealized crystal structure is an unlimited as well as an exact recurrence of the atomic arrangement in the underlying unit cell, real crystal structures contain a variety of defects. The most obvious one, due to the impossibility of infinite structures, is a grain-boundary or the sample surface, which naturally creates contrast by the implied and obviously inevitable change in crystal potential. In general, crystal defects are point-like, linear, planar or three-dimensional modifications of the ideal structure within a single crystal. While local point defects, such as Schottky or Frenkel defects, are usually not visible in the TEM, except when they are locally agglomerated, line defects like screw and edge dislocations or planar defects such as stacking faults and anti-phase domain boundaries are easily observed. *Dislocations* can be described as local positions of atoms being displaced by a vector R from their ideal position in the crystal lattice. This displacement results in an additional phase shift given by $\Phi = 2\pi gR$, with the reciprocal lattice vector g and the displacement vector R . If Φ is not equal to zero, this additional phase shift can be observed as contrast in bright- or dark-field TEM. However, if $g \cdot R$ is zero, the dislocation itself is not visible. Hence it must be noted that, not seeing a dislocation does not mean it is not there! This is the so-called *invisibility criterion*, as illustrated in Fig. 13.

While this criterion is sufficient for pure screw dislocations, invisibility of mixed or pure edge dislocations additionally requires $g \cdot R \times u = 0$, with u being a lattice vector describing the direction of the dislocation line. By utilizing these criteria, it is possible to determine the specific displacement vector of the dislocation, the so-called *Burgers vector* giving $g \cdot b \times u = 0$. Furthermore, when the direction of the dislocation line u is known, the dislocation type can be determined as well. For edge dislocations, u and b are perpendicular to each other, while they are parallel for screw dislocations. In the case of pure edge or screw dislocations, the dislocation line is straight and u can be determined from trace analysis of the dislocation line by comparing at least two images with corresponding diffraction patterns in different orientations. However, it should be noted that mixed dislocations, which have both edge and screw components and bent dislocation lines, implying a variation of u , more frequently occur than pure edge or screw dislocations.

Fig. 13 Illustration of the invisibility criterion: (a) $g = (0\bar{1}\bar{1})$ two-beam bright-field image of $(\bar{1}\bar{1}0)[\bar{1}\bar{1}0]$ and $(101)[10\bar{1}]$ edge dislocations in a pseudo-cubic KNbO_3 single crystal. The invisibility criterion is not fulfilled in (a) and both types of dislocations create contrast. The insets display the corresponding diffraction patterns with the respective g vectors indicated. (b) Using $g = (00\bar{2})$, the edge dislocations with $u = [001]$ are invisible due to $(00\bar{2}) \cdot [\bar{1}\bar{1}0] = 0$ and $(00\bar{2}) \cdot [\bar{1}\bar{1}0] \times [001] = 0$. (c) Using $g = (0\bar{2}0)$, the edge dislocations with $u = [010]$ are invisible due to $(0\bar{2}0) \cdot [10\bar{1}] = 0$ and $(0\bar{2}0) \cdot [10\bar{1}] \times [010] = 0$.

Fig. 14 Illustration of the Burgers circuit: start (S) and endpoint (E) of the Burgers circuit are shown around an edge dislocation line. Start and endpoint do not coincide and the displacement vector pointing from S to E equals the Burgers vector.

Since high-resolution TEM imaging allows a detailed investigation of local crystal structures, it can also be used to determine the Burgers vector of edge dislocations by the so-called *Burgers circuit*. This method requires a HR-(S)TEM image showing the endpoint of a dislocation line, i.e., the dislocation line needs to be parallel to the direction of view. Upon clock-wise “drawing” a rectangle around the dislocation, with the start point on an arbitrary lattice site and the edge length being a defined number of discrete steps from lattice site to lattice site, start and endpoint will not coincide. The vector pointing from the start to the endpoint is the Burgers vector (see Fig. 14). In contrast to edge dislocations, both points will coincide for screw dislocations and the Burgers vector appears to be invisible (the same as if no dislocation is present at all), which is due to b being parallel to the dislocation line and the viewing direction.

Imaging of dislocations is best done by using the so-called *weak beam dark field* (WBDF) technique. In this special setup, the sample is oriented in such a way that only those lattice planes of a certain reciprocal lattice vector g , with a high excitation error, which are bent due to a nearby dislocation contribute to the image contrast, i.e., appear bright. This so-called $3g$ condition allows the display of the dislocation lines to be sharp and well-defined, as compared to the more diffuse and broad lines observed in conventional bright- or dark-field imaging.

Another origin for defect-related contrast in TEM images is the presence of volume defects such as small precipitates, which distort the crystal lattice in their vicinity and cause the occurrence of sometimes large *strain-field contrast*. For small local strain fields, the corresponding contrast is easy to recognize, since it often resembles the shape of small coffee beans and therefore is termed *coffee-bean contrast*. Fig. 15 shows such a coffee-bean contrast originating from local strain fields in the Lorandite, TlAsS_2 , host crystal, running along specific (001) lattice planes.

Electron Diffraction

Switching from image mode to *diffraction mode* in the TEM can simply be done by “pressing a button”, which appropriately changes the intermediate lens current. In consequence, the focus point of the intermediate lens is moved from the intermediate image plane of the objective lens to its back focal plane and hence the diffraction pattern instead of the image is projected onto the viewing screen (compare also Fig. 5; Hirsch, 1999). By inserting the SAED aperture, the sample area contributing to the diffraction pattern can be limited and a well-defined sample region can be investigated in reciprocal space. This aperture, which is positioned in the 1st intermediate image plane, is demagnified back to the specimen plane by a factor of approximately 50x. Therefore, it is possible to select small and very specific sample areas of down to 200–300 nm in size, such as individual grains or even intergranular phases at grain boundaries and triple junctions. Furthermore, in diffraction mode, it is easy to distinguish between *crystalline* and *amorphous* materials. Due to the missing long-range order in amorphous materials, the diffraction pattern only displays characteristically diffuse rings, representing the varying short- and medium-range order in the amorphous material (Fig. 16(a)). Such ring patterns can be employed to extract the *radial-distribution function* (RDF) of the amorphous material, which describes the probability to find atom pairs as a function of pair separation, providing structural information of the amorphous phase. In contrast, in crystalline materials the electron beam is diffracted by the periodic nature of the crystal lattice according to Bragg’s Law. If a *polycrystalline* material is studied, which features a multitude of randomly orientated crystallites in the illuminated volume, a ring pattern is formed, where each ring around the central beam correlates to a certain lattice plane distance d_{hkl} , as shown in Fig. 16(b).

If only one single crystal is examined, discrete diffraction spots will be imaged in reciprocal space, where every diffraction spot correlates to a specific lattice spacing distance (Fig. 16(c)) and the corresponding integrated diffraction intensity (Vincent

Fig. 15 TEM bright-field images of coffee-bean contrast in a Lorandite TIAsS_2 single crystal, originating from local strain fields along specific (001) lattice planes; (b) higher magnification with the corresponding SAED pattern as inset.

Fig. 16 Selected area diffraction (SAED) patterns of (a) an amorphous polymer-derived ceramic featuring the characteristic halo ring pattern; (b) a polycrystalline, simple cubic powder sample of TiCl with consecutive, continuous rings. Note that the distance from the center (incident beam) to these rings allows the determination of the d -spacing of the crystal lattice. In (c), an individual grain within a polycrystalline $(1-x)\text{Na}_{0.5}\text{Bi}_{0.5}\text{TiO}_3 - x\text{BaTiO}_3$ ($x=0.03$) ceramic (lead-free ferroelectric) is shown, featuring a pattern of sharp diffraction spots typical for single crystalline materials. The $1/2\{000\}$ superlattice reflections of this crystal structure are indicated by arrows.

Fig. 17 Schematic diagram showing the scattering geometry for a thin TEM-foil normal to the incident electron beam. The graph on the right reveals the intensity variation of the diffracted beam depending on the deviation from the exact Bragg condition, given by the excitation error s .

and Midgley, 1994). The spacing between the lattice planes d_{hkl} equals the inverse length of the reciprocal lattice vector g_{hkl} given by:

$$d_{hkl} = \frac{1}{|g_{hkl}|} \quad (25)$$

For a detailed interpretation of diffraction patterns, the *Ewald sphere construction* is the usual method applied. The diameter of the sphere is defined by the wave vector k with its length being equal to the reciprocal wavelength of the accelerated electrons: $|k| = \frac{1}{\lambda}$. The wave vector $k' = k + g$, starting from the center of the Ewald sphere, points to a reciprocal lattice point (Fig. 17). If this reciprocal lattice point lies on the circumference of the sphere, the Laue criteria and the Bragg equation are fulfilled and diffracted intensity, i.e., a diffraction spot will be visible. Due to its relation to the wavelength, the radius of the Ewald sphere in TEM is very large as for example compared to X-ray diffraction. Therefore, the sphere can be approximated as an almost flat plane intersecting a multitude of reciprocal lattice points in the Zero Order Laue Zone (ZOLZ) at once (see also Fig. 20). In consequence, not only one individual, but a number of diffraction spots are simultaneously visible, generating a pattern related to the specific symmetry of the illuminated single crystal in its respective orientation.

Theoretically, the diffraction spots are solely mathematical points in reciprocal space. However, due to the very small thickness of the TEM foil, it can be mathematically proven that these points are elongated parallel to the optical axis (z-direction) with a rotational elliptic shape, so-called *relrods* (reciprocal lattice rods). If a relrod is cut by the Ewald sphere, a corresponding diffracted beam exists with its intensity being determined by the deviation from the exact Bragg condition, which is measured by the vector of the excitation error s . For $s \neq 0$, the diffraction vector g does not lie directly on the Ewald sphere and the deviation from the exact position on the sphere is described by the actual scattering vector $K = g + s$. If g lies outside the Ewald sphere, s is negative and if g lies within the Ewald sphere, s is positive. When the crystal is tilted, the reciprocal space sweeps through the Ewald sphere with the excitation error s changing from $+s$ to $-s$ and vice versa.

In order to evaluate s , another characteristic of the diffraction mode in TEM can be deployed: the *Kikuchi lines*. When the incident beam interacts with the sample, besides elastic scattering, also *inelastic scattering* occurs. These inelastically scattered electrons (incoherent beams) can subsequently be diffracted by a set of lattice planes (hkl), which coincidentally is in Bragg condition. In consequence, two diffraction cones are formed, the so-called *Kossel cones*, which correspond to $+g$ and $-g$ and thus to (hkl) and $(\bar{h}\bar{k}\bar{l})$. They also intercept with the Ewald sphere forming a pair of Kikuchi lines (Fig. 18(a)). The line closest to the incident beam is called *deficiency line*, since it has an intensity even lower than the surrounding background of diffuse scattering, while the one further away is termed *excess line* due to its comparably high intensity. Simplified, this phenomenon can be understood by the fact that inelastic scattering occurs predominantly in the forward direction and the excess line ($+g$) contains, in contrast to the deficiency line ($-g$), Bragg-diffracted electrons from such rather forward-biased incoherent beams. When $s = 0$, the deficiency Kikuchi lines run directly through the primary beam and the excess line through the corresponding diffraction spot. When $s \neq 0$, the lines deviate from this position (Fig. 18(b)); for $s > 0$, the line pair moves further away from the direct beam in the direction of the diffracted spot, while it moves in the opposite direction for $s < 0$.

Furthermore, under certain conditions, two excess or two deficiency lines from Kikuchi line pairs corresponding to lattice planes (hkl) and $(\bar{h}\bar{k}\bar{l})$ can together form an excess or deficiency Kikuchi band, respectively. Note that the term Kikuchi band is also often imprecisely used to describe Kikuchi line pairs and the area between them. Since the positions of Kikuchi lines and bands with regard to the direct beam reflect the deviation from the respective g vectors and, hence, the actual orientation of the reciprocal lattice, they can be utilized to easily orientate crystalline samples into crystallographic zone axis conditions. In the case of a perfect zone axis condition, which is usually desirable for SAED patterns, the Kikuchi bands that correspond to the diffraction spots in the pattern, cross each other at the center of the direct beam. Hence, in order to orientate the sample, it just needs to be tilted in such a way that the merging point of the respective Kikuchi band is positioned in coincidence with the direct beam. Note that in perfect

Fig. 18 (a) Schematic illustrating the origin of Kikuchi lines (Kossel cones) and (b) diffraction pattern of a bixbyite single crystal (Mn,Fe)₂O₃ from a thicker sample area (inelastic scattering), showing the presence of a Kikuchi line pair for $s > 0$. Note that these line pairs can be used to easily orientate the crystal in a zone axis or a $s_{hkl} = 0$ condition.

Fig. 19 Comparison of (a) a SAED diffraction pattern with parallel illumination of the sample and (b) a CBED pattern (focused beam) from a [001] zone axis of a β -Si₃N₄ crystal taken at 200 kV. Note that both diffraction images show a sixfold symmetry (Friedel's law $I_{hkl} = I_{\bar{h}\bar{k}\bar{l}}$). The schematic drawings illustrate the corresponding convergence of the electron beam.

zone axis condition, for none of the diffracted beams $s_{hkl} = 0$ is valid; it rather resembles a compromise leveling out all excitation errors to obtain a point-symmetric diffraction pattern with evenly distributed intensities. Furthermore, it should be noted that, in addition to inelastic scattering, Kikuchi lines can also be induced by illuminating the sample with an intense convergent beam, rendering this method of orientating the sample readily available in almost every case.

While SAED patterns, as shown in Fig. 19(a), are generated using a parallel electron beam, so-called *convergent beam electron diffraction* (CBED) patterns are formed when a focused, i.e., convergent beam is used; see for example: Edington (1975), Spence and Zuo (1992), Loretto (1994), Fultz and Howe (2007), Reimer and Kohl (2008). Utilizing the spot-like illumination of such a focused beam (Fig. 19(b)), it is possible to select sample areas even smaller than feasible with the smallest SAED aperture. Therefore, the terms μ -diffraction or nano-diffraction are also commonly used for this technique. Due to the convergent beam setting in CBED, diffraction disks instead of diffraction spots are formed. For a convergent angle α smaller than the diffraction

angle θ , separated non-overlapping disks are observed. The corresponding diffraction pattern is called a *Kossel-Möllenstedt diagram*. For higher convergence angles, the individual diffraction disks overlap, forming a *Kossel diagram*. The disks can exhibit characteristic details, e.g., diffraction lines that carry additional information about the specific crystal symmetry, which is beyond those data obtainable from normal SAED patterns under parallel illumination.

Another difference between CBED and SAED is the excitation of different g_{hkl} diffraction vectors in CBED, which are not necessarily perpendicular to the optical axis due to the high convergent angle α . Therefore, not only diffraction spots from the *Zero Order Laue Zone* (ZOLZ) are visible in CBED (where the Ewald sphere intersects the crystal lattice at the 000-position), but also diffraction information from *Higher Order Laue Zones* (HOLZ) can be displayed (1st, 2nd, etc. lattice planes above the 000-plane), giving information about the third dimension of the crystal parallel to the z-direction, as depicted in Fig. 20. Note that with the projected distance D_s , the distance of the reciprocal lattice plane that lies perpendicular to the incident beam direction can be calculated with:

$$D_s = \sqrt{2n \frac{g_{hkl}}{\lambda}} \rightarrow g_{hkl} = \frac{D_s^2 \lambda}{2n} \quad (26)$$

where g_{hkl} is the distance to be calculated, n is the order of the Laue zone and λ is the electron wavelength.

Under certain circumstances, CBED allows for the determination of the point and space group symmetry. For example, with the help of CBED, it is possible to distinguish between trigonal α -Al₂O₃ with space group $R\bar{3}c$ and hexagonal α -SiC with space group $P6_3mc$. In a conventional SAED pattern, a 6-fold symmetry is displayed in both cases, because regular SAED diffraction patterns are strictly centrosymmetric according to Friedel's law (intensity $I_{hkl} = I_{\bar{h}\bar{k}\bar{l}}$; Laue symmetry), while in CBED mode, the 3-fold symmetry of alumina becomes visible by the faint HOLZ lines within the central diffraction disc.

A versatile but rather complicated CBED method, which is especially suitable for the investigation of dislocations and other defects, is *large angle convergent beam electron diffraction* (LACBED). In simple words, this technique utilizes a combination of

Fig. 20 (a) Schematic of the Ewald sphere construction for a convergent incident electron beam showing the origin of Higher Order Laue Zones (HOLZ). The intersection of the Ewald sphere with the Zero, First and Second Order Laue Zones are shown. Note that the projected distance D_s allows determination of the spacing of the reciprocal lattice planes g_{hkl} along the electron beam direction (Eq. 26). (b) CBED pattern of a SiC crystal revealing the Zero (ZOLZ), First (FOLZ) and Second Order Laue Zone (SOLZ).

Fig. 21 LACBED image of a $[0\bar{1}1][\bar{1}11]$ edge dislocation in a pseudo-cubic KNbO₃ single crystal. The identification of the diffraction lines g_{hkl} (light blue) intersecting the dislocation (marked in red) allows the calculation and determination of the Burgers vector b , based on the number of interfringes n at the intersection point.

imaging and diffraction effects, which is induced by employing a large beam convergence angle of 1° to 5° , a highly defocused beam or offset z-height, and the selection of only the direct beam by the SAED aperture. The resulting LACBED image contains diffraction lines (deficiency lines only) as well as a BF image of the illuminated area. By carefully tilting the specimen, the diffraction lines are moved with respect to the image in such a way that they intersect the dislocation of interest (Fig. 21).

At the intersection point, a diffraction line corresponding to a certain g_{hkl} is twisted and interrupted n times depending on the Burgers vector b according to:

$$g_{hkl} * b_{uvw} = h * u + k * v + l * w = n \quad (27)$$

with $n \in \mathbb{N}$. While the absolute value of n simply equals the number of interfringes, the sign of n depends, according to the so-called *Cherns-Preston rules*, on the twist character, the direction of the dislocation line u , and the direction of the deviation parameter s (excitation error) for the respective g_{hkl} line. If at least three identified and appropriately different diffraction lines are investigated and their corresponding n is determined, an equation system can be set up which allows the calculation of the three unknown variables u, v, w and hence the determination of b . If performed thoroughly, this method is very distinct and works well not only for edge, screw and mixed dislocations, but also for stacking faults and anti-phase domain boundaries (APBs). However, since the number of visible diffraction lines can be very high, it typically requires the simulation of LACBED images beforehand, in order to unambiguously identify the chosen g_{hkl} lines. A detailed introduction to this powerful technique and its applications can be found in Morniroli (2018).

High-Resolution Imaging

For *high-resolution imaging* in TEM (HRTEM), which is usually conducted at magnifications higher than 150,000x, the observable image contrast is correlated to a phase shift of the incident electron wave. Therefore, the contrast in this imaging mode is termed *phase contrast* (Buseck *et al.*, 1988; Williams and Carter, 2009; Spence, 2013), as opposed to the *amplitude contrast* discussed earlier. The essential part of the total phase shift is generated as the direct beam passes through the sample volume. However, as the electron beam travels through the microscope, an additional phase shift is introduced by the spherical aberration r_s and the focus setting of the objective lens (defocus Δf), generating contrast in the HRTEM image. Interference of the differing phase vectors of the exiting electron waves from the direct and the various diffracted beams then results in altered amplitudes, which makes the phase contrast visible and creates the observed image (cameras as well as the human eye can only detect amplitude contrast). Since

Fig. 22 The plot $\sin\chi(u)$ versus u and the corresponding HRTEM micrographs of the identical area of a boron suboxide B_6O single crystal imaged at different defocus values: (a) at a defocus value of $\Delta f = -20$ nm and (b) at Scherzer defocus $\Delta f = -50$ nm ($E_0 = 200$ kV, $C_s = 2.3$ mm). The colored areas in both plots of $\sin\chi(u)$ versus u indicate the resulting negative contrast shown in (a) versus a positive contrast in (b) for the spatial frequency u_1 . Note that, by convention, negative contrast describes the case when the atoms appear bright on dark background (going back to the times, when film negatives were used to record the images). The arrows in the HRTEM images indicate stacking faults in the B_6O structure, proving that identical areas are imaged in (a) and (b). The insets show a higher magnification.

the image contrast is strongly linked to the focus setting and the thickness of the specimen, HRTEM images, in general, cannot be intuitively interpreted (compare also Fig. 22).

The spatial information from a single point of the specimen is projected onto the screen or a CCD camera as an extended region, the Airy disc, mainly due to the existing lens imperfections. Each point in the specimen can be described by a specimen function $f(r) = f(x, y)$. The intensity in the image that corresponds to a point (x, y) within the specimen is described by the image function $g(r) = g(x, y)$, given by:

$$g(r) = \int f(r')h(r-r')dr' = f(r) \otimes h(r) \quad (28)$$

where $h(r) = h(x, y)$ is the *point spread function* (or *smearing function*), used as a measure for the contribution of a specimen point (x, y) to the image, being convoluted with $f(r)$. Assuming uniform coherent illumination, the specimen function can generally be described with respect to the amplitude $A(x, y)$ and the phase $\phi_t(x, y)$ of the electron wave:

$$f(x, y) = A(x, y)e^{(-i\phi_t(x, y))} \quad (29)$$

Since the contrast in HRTEM is created by a phase shift and not by a change in amplitude, as is the case for the amplitude contrast in for example bright-field imaging, the amplitude term $A(x, y)$ can be set to 1. The phase shift that is generated while the electron beam passes the specimen, depends on the specimen potential $V(x, y, z)$ the electron sees. For very thin samples of thickness t , the projected potential $V_t(x, y)$ is used and the specimen transfer function can then be rearranged as:

$$f(x, y) = e^{[-i\sigma V_t(x, y) - \mu(x, y)]} \quad (30)$$

Here, the specimen is described as an independent phase object, termed the *phase object approximation* (POA). The variable σ is called the *interaction constant* and depends on the electron wavelength and acceleration voltage E , which can be expressed as $\sigma = \pi/\lambda E$. The function $\mu(x, y)$ considers the absorption, which occurs when the electron beam passes through the specimen volume. For very thin specimens with $V_t \ll 1$, the absorption contribution can be neglected and $f(x, y)$ can be simplified to the following expression termed the *weak phase object approximation* (WPOA):

$$f(x, y) = 1 - i\sigma V_t(x, y) \quad (31)$$

Using the WPOA model and applying this term to Eq. 28, the wave function as observed in the HRTEM image can be expressed by:

$$\Psi(x, y) = [-i\sigma V_t(x, y)] \otimes h(x, y) \quad (32)$$

The intensity distribution in the recorded HRTEM image is given by $I = \Psi\Psi^* = |\Psi|^2$. When multiplying this out, substituting $h(x, y)$ by $\cos(x, y) + i\sin(x, y)$ and neglecting the σ^2 terms, since σ is rather small, the equation can be rearranged and reduced to:

$$I = 1 + 2\sigma V_t(x, y) \otimes \sin(x, y) \quad (33)$$

The *contrast transfer function* $H(u)$ is a Fourier transform of $h(r)$, with u being the spatial frequency. Hence, for a certain direction, $H(u)$ is described by the product of the aperture function $A(u)$, the envelope function $E(u)$, which accounts for the damping property of the objective lens system, and the aberration function $B(u)$:

$$H(u) = A(u)E(u)B(u) \quad (34)$$

Taking Eq. 32 into consideration, the *objective lens transfer function* $T(u)$ can be derived. Here, only the imaginary part of $B(u) = e^{i\chi(u)}$ is considered, since it contributes to the intensity of the image. When the aberration function $B(u)$ is further set to $B(u) = 2\sin\chi(u)$, it follows for the transfer function $T(u)$:

$$T(u) = A(u)E(u)2\sin\chi(u) \quad (35)$$

The term $\chi(u)$, also called the *phase distortion function*, describes the shift of the electron phase vector in the specimen, depending on the defocus of the objective lens Δf , the spherical aberration coefficient C_s , the electron wavelength λ , and the spatial frequency u :

$$\chi(u) = \pi\Delta f\lambda u^2 + \frac{1}{2}\pi C_s\lambda^3 u^4 \quad (36)$$

Fig. 22 illustrates how the objective lens transfer function and the information in the high-resolution TEM image correlate with each other.

Here, $\sin\chi(u)$ is plotted versus u , the spatial frequency. The area between $u = 0$ and the value for u , where $\sin\chi(u)$ intersects the zero line for the first time, u_{int} , is termed the zero-order *passband*. The first intersection point defines the *resolution limit* of the lens system, being $d_{min} = 1/u_{int}$.

From Eq. 36 it can be seen that $\sin\chi(u)$ is predominantly coupled to the defocus Δf , because the spherical aberration coefficient C_s is a constant (for a given TEM instrument), and the electron wavelength λ can at first approximation also be assumed constant. To some degree, defocusing the objective lens allows for a partial compensation of the effect of the spherical aberration. This was first discovered by Otto Scherzer in 1949 and the defocus value for the optimum resolution, the so-called *Scherzer defocus*, is named after him (Scherzer, 1949). The corresponding resolution limit can then be described as:

$$\Delta f_{Scherzer} = -1.2(C_s\lambda)^{\frac{1}{3}} \text{ giving } d_{min} = 0.66(C_s\lambda^3)^{\frac{1}{4}} \quad (37)$$

In order to be able to apply the weak phase object approximation and to interpret the HRTEM image recorded, the TEM specimen thickness has to be reduced to an absolute minimum, since the WPOA directly correlates to the specimen volume, which is required

Fig. 23 HRTEM micrographs of (a) β - Si_3N_4 and (b) BaTiO_3 with real atomic positions shown as inset. The simulation revealed that depending on the defocus employed, positive phase contrast occurs in both cases; however, in (a) the bright contrast in the image is related to intrinsic channels in the structure, while in (b) the contrast coincides with the real atomic positions of Ba and Ti. Note that in (b) the oxygen cannot be seen due to its low scattering intensity.

to be very small. Then the contrast in the image, consisting of bright and dark structures, is directly linked to the objective lens transfer function. If $T(u)$ is negative within the zero-order passband, positive image contrast arises. This means that atoms appear black on a bright background, whereas they appear as bright spots on a dark background when $T(u)$ is positive, which creates a negative contrast. If $T(u) = 0$ is valid, no contrast arises for the corresponding value or range of u , even if there are atoms positioned at exactly this spatial frequency. From the value of u , which corresponds to minima and maxima of the lens transfer function due to the oscillating nature of $T(u)$, the atomic distance between bright (or dark) spots in the image can be derived. In the HRTEM images shown in Fig. 22, negative respective positive contrast contributes to the final image (here shown for the spatial frequency u_1).

In order to interpret the observed contrast correctly, especially when questions regarding the location of specific atomic positions are addressed, it is often necessary (as well as helpful) to conduct image simulations of the investigated sample. Fig. 23 shows two examples, where the actual atom positions are indicated and correlated with the bright intensities in the HRTEM images.

To enable a direct comparison between the obtained HRTEM and the simulated image, it is necessary to know the specific experimental parameters such as the defocus value, sample thickness and the spherical aberration of the objective lens (Cowley and Moodie, 1957). In order to model the interaction of electrons and atoms within the specimen, a commonly applied simulation method is the *multi-slice approach* (Stadelmann, 1987; Kirkland, 1998; Koch, 2002). Here, the specimen is virtually cut into thin slices perpendicular to the electron beam and the interaction of the propagating electron wave with each slice, resulting in a phase shift according to the WPOA model, is calculated. Other simulation methods include (1) the Bloch wave approach, (2) the reciprocal or real space approach or (3) the FFT formalism. By using such simulation techniques and knowing the exact atomic positions of the investigated crystal structure, the corresponding image intensities can be calculated and the result can directly be compared to the experimentally observed contrast in the HRTEM micrograph. As shown in Fig. 23(a), the bright spots that give a hexagonal array do not correlate with any atomic position in the β - Si_3N_4 crystal structure, but rather represent channels in the crystal, running parallel to $[001]_{\text{Si}_3\text{N}_4}$ and along the optical axis of the microscope. In contrast, the bright contrast in the HRTEM image of BaTiO_3 in Fig. 23(b) coincides with the actual positions of the Ba and Ti atoms/ions.

Concluding Remarks

We hope that we have succeeded to arouse your interest and at the same time convinced you of the power and versatility of transmission electron microscopy for detailed characterizations of ceramics, glasses and other solid-state materials. Perhaps in the future you will become a fervent advocate and user of this technique and if so, discover that TEM is indeed far more versatile than we were able to illustrate in this short introduction.

Analytical Transmission Electron Microscopy

Analytical Electron Microscopy (AEM) describes the collation of techniques with which spatially resolved spectroscopic information of a sample can be acquired and quantified. In addition to revealing the structure of materials, information about their elemental composition, bonding state and bandstructure can be obtained on a highly spatially resolved level, via spectroscopic methods carried out in the Transmission Electron Microscope (TEM), e.g., Energy Dispersive X-ray spectroscopy (EDX) and Electron Energy Loss Spectroscopy (EELS).

These analytical assessments can be carried out quantitatively alongside TEM and High-Resolution Transmission Electron Microscopy (HRTEM) imaging. Beyond this, AEM can be carried out on an unprecedented temporospatially resolved scale, providing spectroscopic information down to the atomic scale, when carried out in combination with Scanning Transmission Electron Microscopy (STEM), especially in Angular Dark Field (ADF) and High Angle Annular Dark Field (HAADF) imaging mode. HAADF, alone, reveals elemental information about the material, due to the impact of the material's atomic number on the elastic scattering intensity and direction of the traversing electron beam. This then reveals the materials properties in terms of chemical composition. Fig. 1(a) shows a sketch of the principal interactions of the electron beam with the TEM specimen, with emissions utilized for EDX, EELS and HAADF detection indicated by red, blue and green arrows, respectively.

After its transmission through the sample and having passed through the annular (HAADF and ADF) detectors, the undeviated (not elastically scattered) e-beam, a great part of which has lost energy due to inelastic scattering events, enters a magnetic 90° prism (Fig. 1(b)), which is part of the electron energy loss spectrometer. The magnetic field of the prism bends the electron beam to a larger or smaller extent, according to the larger or smaller energy losses inflicted by the sample. Monitoring the intensity of the outcoming beam at varying beam directions along the axis across a detector, provides a display of these intensities as a function of energy loss, i.e., resulting in the acquisition of an energy loss spectrum (right most feature in Fig. 1(b)).

In this chapter, the fundamental aspects and recent applications of STEM and HAADF, especially on the highly spatially resolved level, as well as of EDX and EELS will be addressed.

Fig. 1 (a) This schematic details some of the scattering events that happen when an electron beam interacts with a TEM specimen. The scattering events that contribute to AEM (and focused on in this chapter) are X-rays (red) which are captured by a (usually) side-entry EDX detector (four quadrant detectors are available in newer instrument setups and shown here gray-ed out), coherent elastic scattering (green) at high angles and captured by a high angle annular detector used for HAADF-STEM imaging, and inelastic scattering (blue) which follows the trajectory of the undeviated beam, passing through the annular HAADF detector to (b) an EELS spectrometer. Schematics amended from reference. Bluescientific, 2020. Gatan Advanced STEM Detectors. Fig. 2 An illustration showing the instrumental design of the dedicated STEM. Unlike the conventional TEM with STEM capabilities, the electron source of a dedicated STEM is positioned at the bottom. Reproduced from Bangert, U., Gass, M., Zan, R., Pan, C.T., 2011. Scanning transmission electron microscopy and spectroscopy of suspended graphene. In: Mikhailov, S. (Ed.), *Physics and Applications of Graphene – Experiments*. Rijeka: IntechOpen pp. 377–408.

Principles of Scanning Transmission Electron Microscopy (STEM)

STEM can be carried out in TEM instruments with scanning probe capacities, or in an instrument, which is designed for TEM measurements to be carried out solely in scanning mode (known as a dedicated STEM), a sketch of which is shown in Fig. 2. Due to their specific layout STEM instruments can only be operated in scanning mode (for imaging and analytical measurements). This design provides high operational stability, because the instrument does not need to be switched between imaging and scanning mode, which often requires re-alignment of imaging and spectroscopy parameters. In STEM mode a narrow beam (of diameter < 1 nm) is scanned across a sample in a rastering fashion. Modern aberration corrected, dedicated STEM instruments produce a beam diameter of down to $1 \text{ \AA}$ owing to a probe corrector, which reduces the high order aberrations (Brydson, 2011). The objective lens recombines the transmitted, primary electrons from every point scanned by the probe to a fixed region in the back focal plane, where an electron detector captures them. STEM imaging can typically be carried out using various modes depending on the collection angle of the transmitted beam and the available detectors. In the High Angle Annular Dark Field (HAADF) mode the HAADF imaging detector is used (see Figs. 1(a) and 2) (Bangert *et al.*, 2011). STEM can also be carried out in Bright Field (BF) mode, where the intensity of the undeviated beam (Fig. 1(a)) is monitored at each scan point. Imaging in scanning mode results in a 2D array of pixel intensities, which, when displayed altogether, constitute an image contrast map. The BF-STEM mode can be correlated with the conventional parallel beam TEM mode. BF-STEM contrast provides a direct comparison with, and opposite to, the Z-contrast in HAADF-STEM imaging, the latter revealing the atomic number of the material.

In HAADF-STEM imaging mode electrons that have been elastically scattered into high angles (sketch in Fig. 1(a)) are detected with annular detectors (a.k.a., doughnut detectors), therefore excluding the undeviated beam, and also the electrons inelastically scattered into small angles whose function will be explained later with respect to EELS. HAADF imaging in scanning mode can be carried out at *atomic resolution*, revealing the chemical nature of individual atoms, because of the relationship between the scattering intensity (I) and the atomic number (Z), as $I \propto Z^2$, (more accurately $I \propto Z^{1.7}$) (Williams and Carter, 1996; Egerton, 2011). The contrast in atomic resolution BF and HAADF-STEM images is in reverse, i.e., in BF, positions of atoms appear dark since the electron beam is scattered outside the collecting aperture, whereas in HAADF-STEM the atomic positions appear bright, since the electrons reaching the high angle angular detector are scattered into higher angles by the atoms, thus here the dark areas indicate absence of electron scattering.

Fig. 3(a) and (b) show atomic resolution BF-STEM and HAADF-STEM micrographs, respectively, of lanthanum calcium cobalt oxide (LCCO) perovskite with the electron beam entering the crystal along the $[110]$ direction. The images display $[110]$ projections of the crystal (see the unit cell in Fig. 3(c)), showing an example of the reverse contrast that distinguishes BF from HAADF-STEM images. Fig. 3(d) is an enlargement of the area in the red frame indicated in Fig. 3(b), where the atomic columns projected along the $[110]$ direction of the electron beam appear as bright dots. The model of the unit cell with its zone axes and different color elements is shown in Fig. 3(c). The unit cells viewed along the $[110]$ direction (the direction of the incoming electron beam) is overlaid on the atomic columns revealed in the image in Fig. 3(d). According to the contrast, which scales with the Z -number of the elements as $Z^{1.7}$, the columns containing La and Ca, additionally interlinked with O, when projected along the $[110]$ direction

Fig. 3 A direct comparison of (a) BF-STEM and (b) HAADF-STEM imaging of the perovskite material lanthanum calcium cobalt oxide (LCCO). (c) the unit cell of the material is shown (Co – yellow, Ca/La – blue, O – red) with the electron beam entering along the [110] direction. (d) A higher magnified image of the area indicated by the red box in (b) with the unit cell model overlaid in the [110] plane. Amended from reference Bangert, U., Falke, U., Weidenkaff, A., 2006. Nature of domains in lanthanum calcium cobaltite perovskite revealed by atomic resolution Z-contrast and electron energy loss spectroscopy. *Materials Science and Engineering: B* 133, 30–36.

(red dots on blue in Fig. 3(d)), are the brightest, followed by the less bright contrast of the Co columns (yellow dots), and the columns containing only O are dark (red dots). The bright and dark boundary in Fig. 3(a) and (b), respectively, can be seen at the higher resolution in the HAADF-STEM micrograph in Fig. 3(d), to be a boundary between different crystal domains.

In HRTEM, apart from the regular contrast variations on the Ångström scale representing atomic columns, contrast variations on the larger scale, which impact on, and change the HRTEM contrast, can also be seen (Fig. 4). These contrast changes arise from thickness variations as well as from diffraction effects, in places, where the TEM sample is slightly bent, leading to deviations from the exact zone axis orientation. This contrasts with (and compliments) HAADF-STEM, where intensities are due to the elemental nature of the atoms in the material.

In Fig. 4, a selection of HRTEM micrographs is displayed (the HRTEM technique is explained in the previous chapter), showing the nanostructure of grain boundaries and intergrowth in layered, machinable and electrically conductive Ti_2AlC and Ti_3AlC_2 ceramics (Wang and Zhou, 2010). HRTEM allows clear identification of the misorientation of the [001] plane in Fig. 4(a). At a higher magnification the intergrowth between Ti_3AlC_2 and Ti_2AlC can be identified by simply referring to the unit cell configuration and noting, in this case, that the Ti layers are separated by three Al layers in Ti_3AlC_2 and by two Al layers in Ti_2AlC . Another example of ceramic intergrowth of TiC can also be identified between two domains of Ti_2AlC in Fig. 4(c).

Electro-magnetic lenses used in electron microscopes are inherently imperfect compared to glass lenses in optical microscopes, leading to, e.g., spherical and chromatic aberrations. In order to achieve atomic resolution, as shown in the images presented in this section, these aberrations need to be corrected. Explained in simplistic terms, this can be achieved by adding lenses with “inverse” imperfections after, e.g., the objective lens, acting as an image corrector, or after the condenser lens, acting as probe corrector. The electron beam has furthermore, an energy spread, which has consequences, especially for analytical and spectroscopic investigations, and can be corrected by addition of a monochromator (after the electron gun). Modern TEMs have image and probe correctors as well as a monochromator. Using aberration corrected and monochromated TEM, information of the atomic structure can be obtained down to the sub-atomic, i.e., Ångström scale, revealing, shifts in atomic positions, which can lead to atomic dipole constellations, e.g., in ferro-electric materials, which are sought after for applications in next generation IT components, e.g., capacitors, mobile nano-switches and nano-sensors (Chen et al., 2017; Zhao et al., 2019; Guan et al., 2020).

To achieve reliable atomic resolution HAADF-STEM images, the benefit of minimizing and eliminating high order aberrations can be seen. Although atomic resolution TEM and STEM observations reveal *qualitative* information about the atomic structure of

Fig. 4 HRTEM images of (a) a grain boundary in Ti_2AlC revealing misorientation of the [001] plane, (b) intergrowth of Ti_2AlC and Ti_3AlC_2 , confirming, by the distance between the intergrowth boundaries, the existence of two Al layers in Ti_2AlC and 3 Al layers in Ti_3AlC_2 and (c) intergrowth of TiC sandwiched between Ti_2AlC . Amended from Wang, X.H., Zhou, Y.C., 2010. Layered machinable and electrically conductive Ti_2AlC and Ti_3AlC_2 ceramics: A review. *Journal of Materials Science & Technology* 26, 385–416.

materials, in order to confirm this *quantitatively* and to ensure appropriate interpretation of HRTEM and HRSTEM images, as well as to prove the agreement with theoretical models and predictions, image simulations are required.

Fig. 5 demonstrates how simulations of HAADF-STEM images can supplement and/or verify observations made in experimental images. Open source simulation software such as Dr. Probe can be used as a method to verify the observations in experimental images of known materials (Barthel, 2018). **Fig. 5(a)** displays a micrograph of a monolayer of MoS_2 , doped with Se ions via an experimental technique known as ion-implantation. Ion implantation is an indispensable method, employed since several decades, to dope semiconductor materials for device manufacture for IT, and is applied here to controllably dope monolayer materials to tailor them for nano-opto-electronic applications, in this case to achieve single photon emitters.

The enlarged overlaid image of the area in the red frame shows different types of imperfections in the MoS_2 lattice. These are indicated by the colored arrows, i.e., red – a Se atom in a chalcogen position, blue – an unidentified foreign atom in a Mo position, green – an unidentified foreign adatom and yellow – a sulfur divacancy. The molecular model of MoS_2 is overlaid, with S atoms (two S atoms overlaid) in yellow, Mo atoms in blue and Se-implants in red. The Z^2 dependency of the contrast of elements with the corresponding atomic numbers is distinctive when scrutinizing the materials in HAADF-STEM. The above example is a good indication of how clear the distinction can be made by the human eye; however, simulation techniques are used to confirm this. In **Fig. 5(b)**, each of the atomic constellations in the color-framed boxes agrees quantitatively with the respective (same colored

Fig. 5 (a) a HAADF-STEM micrograph of MoS_2 after undergoing ion implantation with Se. The area in the red box is shown at higher magnification in the inset with the molecular model overlaid. The red, blue, green and yellow arrows correspond to imperfections in the MoS_2 lattice. (b) The imperfections are displayed individually as simulated HAADF-STEM micrographs (enabled by Dr. Probe simulation software), with the red, blue, green and yellow boxes corresponding to the same color arrows in (a). The images are original work from the authors' research group, presented at the Nanotech2019 conference. Enabled by Barthel, J., 2018. Dr. Probe: A software for high-resolution STEM image simulation. *Ultramicroscopy* 193, 1–11.

arrow) arrangements in the HAADF-STEM inset in Fig. 5(a) and provides proof of the information extracted from the experimental HAADF-STEM image, regarding atomic structure and elemental constellations.

Experimental atomic resolution images can be refined to reduce the signal-to-noise ratio by using the Fast Fourier Transform (FFT) technique (De Jong *et al.*, 1989). In the FFT map, the image, which contains regular structures in direct image space, is transformed into a diffraction pattern in reciprocal space. In the FFT map, “masks” are then overlaid on the diffraction spots, eliminating other intensities in the FFT, i.e., arising from noise or other irrelevant diffraction spots, to identify specific lattice projections. When inversely transforming the “masked” FFT, a sharpened, contrast enhanced image is acquired.

Fig. 6 shows an example of how FFT masking can filter a noisy HAADF-STEM micrograph to provide a clearer representation of what atom configurations are expected in Cr_2AlC ceramics when imaging along the $\langle 1\bar{2}10 \rangle$ direction (Fig. 6(b)), resulting in atomic column projections as displayed in the model unit cell in Fig. 6(a). It can be seen that two Cr layers are intercalated and mirrored by Al atomic sheets. The atomic positions of the Cr and Al atomic columns are clearly identified in comparison to the unit cell. An intensity profile is extracted (the plot is shown in the inset in Fig. 6(b)) to show the distinction between the Cr and Al atoms in the lattice via their HAADF intensities, further confirming the stacking sequence of Cr and Al.

In this example the microscope software suite Digital Micrograph (more recent versions are called Gatan Microscopy Suite, a.k.a., GMS3) is used to filter out the noise by using the FFT generated from the image in Fig. 6(b). The filtered image in Fig. 6(c) is presented in a colored schematic related to the image intensities (with brightest intensities in yellow and darkest intensities in blue, according to the temperature scale) to enable a clearer identification of the atomic columns. Fig. 6(c) (like the intensity profile plot in Fig. 6(b)) shows the intensity fluctuations with two strongly intense atomic rows and one of weak intensity, further indicating the layer stacking sequence of Cr and Al, and moreover, the atomic number difference between the *M* and *A* elements in the MAX phases. The atomic number distinction between Al and Cr is relatively large, which allows HAADF-STEM to be an efficient method of identifying the atomic positions and hence stacking patterns of layered ternary ceramics. Grain boundary cores, and thus grain boundary structures have crucial influence on the fracture properties of ceramics. Fig. 7 reveals the atomic-bond breaking path within a dopant-segregated Al_2O_3 grain boundary core, via HAADF-STEM atomic-scale observations of the crack tip interface (Fig. 7(a)), introduced by in situ nanoindentation experiments inside a TEM. The HAADF-STEM image shows an example of the unfractured (blue box), crack tip (yellow box) and fractured (red box) areas in the same image. The unfractured area clearly shows distinction between the atomic columns whereas the crack tip and fractured areas display increased noise and decreased intensity distinction between the atomic columns. The observations show that the atomic fracture path occurs to produce less coordination-deficient oxygen polyhedra of dopant cations, which is also supported by using simulations, i.e., first-principles calculations (Kondo *et al.*, 2019). The fracture paths are overlaid on the material unit cell and indicated by the dashed lines in Fig. 7(b). The findings indicate that the atomic coordination geometry at the grain boundary core affect the fracture process. This is directly compared with the HAADF-STEM image in Fig. 7(c) where the zig-zag fracture geometry (Fig. 7(c) – top, from the schematics in Fig. 7(b) – bottom) and the straight Zr-Zr fracture (Fig. 7(c) – bottom, from the schematics in Fig. 7(b) – top) is overlaid confirming that both have taken place. The observations indicate that the local coordination geometry at the grain boundary core has a strong influence on the selection of the preferential atomic fracture path.

Fig. 6 (a) Unit cell configuration in the $[1\bar{2}10]$ projection, of Cr_2AlC (Cr – blue, Al – orange, C – gray), (b) HAADF-STEM micrograph of Cr_2AlC imaged along $\langle 11\bar{2}0 \rangle$ with an intensity profile taken along the white rectangle and displayed in the inset, (c) FFT filtered image of (b) with intensity dependent temperature-scale colored overlay to more clearly reveal the atomic columns. Fig. 7 After in situ nanoindentation, a Zr doped Al_2O_3 grain boundary was imaged using HAADF-STEM to observe the atomic-scale fracture path; (a) HAADF-STEM micrograph with three highlighted areas identifying the unfractured, crack tip and fractured areas, (b) fracture path models calculated based on cleavage energies showing the three potential fracture paths, Zigzag, Zr-Zr and Zr-Al, (c) a HAADF-STEM image of the fracture surface with the structural models superimposed, identifying that the Zigzag and Zr-Zr fracture paths took place. The scale bars are 0.5 nm. Figures are amended from the reference Kondo, S., Ishihara, A., Tochigi, E., Shibata, N., Ikuhara, Y., 2019. Direct observation of atomic-scale fracture path within ceramic grain boundary core. *Nature Communications* 10, 2112.

Since HAADF Z-contrast depends roughly on the square of the atomic number of the element imaged, it is very well suited to reveal heavy elements and compare these and their positions to elements of different intensities in a compound. However, it is impossible to reveal light elements, e.g., O, N, C using STEM (inclusive of BF and HAADF) alone, due to their weak contrast and susceptibility to irreversible damage from the electron beam amongst other difficulties associated with the high current used for STEM imaging techniques. Therefore, additional imaging techniques can be employed to allow undestructive imaging of light elements, such as the STEM imaging technique, integrated Differential Phase Contrast (iDPC).

Integrated Differential Phase Contrast (iDPC)

Differential Phase Contrast (DPC) imaging is a revolutionary STEM imaging method to visualize an electromagnetic field in a specimen by measuring the deflection of an electron beam due to the field at each beam-scan point. STEM images are collected on pixelated quadrant ring detectors. DPC images are then formed by subtracting intensities on the detector segments diametrically opposed with respect to the optical axis. This converts beam deflection, which relates closely to the gradient of the phase change through the specimen, into image contrast. This relationship arises from the fact that the deflection is caused by the sample's electric field, which is proportional to the potential and the phase differential, i.e., $E \propto \Delta V \propto \Delta\Phi$. So, the subtraction of the signal from opposite quadrants represents the gradient of the potential and phase differential: $(\Delta V_1 - \Delta V_2) \propto (\Delta\Phi_1 - \Delta\Phi_2)$. DPC imaging has been utilized for observations of micrometer to nanometer scale magnetic domains. In recent years, this imaging method has been applied to the analysis of electric fields, and the electric field at the atomic scale has been observed using a transmission electron microscope equipped with a Cs corrector. An iDPC-STEM image, then represents the *scalar* electrostatic potential field of

Fig. 8 (a) iDPC-STEM micrograph of a bismuth based cuprate material; the inset shows an enlarged area of (a) with the atomic model superimposed showing the oxygen positions (red dots) in the CuO_2 planes, (b) and (c) correspond to the red and blue boxes (respectively) from (a) identifying the position of the oxygen dopants. (d) The atomic model of the cuprate is shown with the oxygen dopants (black) and (e) the HAADF-STEM simulation including the positions of oxygen dopants, thus verifying the observations on the experimental iDPC-STEM. Amended from reference Song, D., Zhang, X., Lian, C., et al., 2019. Visualization of dopant oxygen atoms in a $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ superconductor. *Advanced Functional Materials* 29, 1903843.

Fig. 9 iDPC-STEM imaging of a zeolite, ZSM-5. (a) After adsorption of paraxylene, the small hydrocarbons can be seen in the pores of the zeolite structure. (b1) shows an enlarged area of a pore from (a), (b2) shows the calculated structural model of ZSM-5 considering the paraxylene introduction, (b3) shows the corresponding electrostatic potential. (c) To show the desorption and study the adaption of the structure, the sample underwent heating up to 250°C, after which the paraxylene has desorbed from the zeolite material. Reproduced from Shen, B., Chen, X., Cai, D., *et al.*, 2020. Atomic spatial and temporal imaging of local structures and light elements inside zeolite frameworks. *Advanced Materials* 32, 1906103.

the sample, obtained by the 2D integration of the vector image acquired by DPC-STEM, (consisting of two components: DPCx and DPCy), representing the *vector* electric field of the sample.

Therefore by using the iDPC, direct imaging of the phase of the “transmission function” of the material is possible for non-magnetic samples, even resulting in direct interpretation of the electrostatic potential from the images (Yücelen *et al.*, 2018; Lazić *et al.*, 2016). A notable capability of this relatively complex iDPC-STEM technique is the ability to measure piezoelectric polarization fields (Lohr *et al.*, 2012) and to allow atomic resolution imaging of light and heavy elements together with high signal-to-noise ratios at low beam currents, i.e., at $<40 \text{ e}^- \cdot \text{\AA}^{-2}$, which is 2–3 orders of magnitude lower than typical electron doses used in STEM. The relationship between the intensity and the atomic number is (almost) directly proportional, in contrast to the $I \propto Z^{1.7}$ relationship in HAADF-STEM (Shen *et al.*, 2020; Yücelen *et al.*, 2018). For materials such as layered cuprates, where identification of the excess oxygen atoms is crucial in revealing the facilitation of hole doping, iDPC-STEM can accurately determine their positions within the planes for better characterization of these promising superconductive materials.

Fig. 8 directly visualizes the incommensurate atomic structure and (excess) dopant oxygen atom locations in a $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ cuprate (Fig. 8(a)) (Song *et al.*, 2019). The unit cell model of the material is overlaid (inset in Fig. 8(a)) which accurately locates the oxygen positions, which would be impossible to identify with conventional (BF) and HAADF STEM. Specific areas from Fig. 8(a) are shown in Fig. 8(b) and (c) to indicate the positions of the dopant oxygen atoms (indicated by red arrows). Simulated iDPC-STEM was conducted to ascertain the effects of oxygen dopants on the local atomic configuration and the electronic structure (Fig. 8(e)). Local strain analysis explains the favorable positions for dopant oxygen between the BiO and SrO planes, consistent with the experimental iDPC-STEM images. The dopant oxygen atoms (causing hole doping of the CuO_2 planes) are accommodated by shifting the surrounding atoms, especially the oxygen atoms, thus aggravating the local distortions.

For complex lattice structures in porous zeolites, iDPC-STEM can provide significant information to aid their applications in catalysis and energy storage. One such zeolite, ZSM-5, consists of a largely hydrocarbon aromatic framework forming channels that “will influence the sorption and diffusion of small molecules” (Shen *et al.*, 2020). Fig. 9 shows atomic resolution iDPC-STEM images of the local structures of the zeolite framework in the [010] projection upon adsorption of paraxylenes (PXs), which are similar in size to the hydrocarbon pools. iDPC-STEM reveals the low Z element containing paraxylenes in the ZSM framework, verified by the calculated structural model (Fig. 9(b2)) and electrostatic potential (Fig. 9(b3)). In an in situ experiment the PXs were desorbed from the ZSM-5 framework by heating the material from room temperature to 250°C, and the same area (before and after heating) was imaged. This is the first time that small aromatics and their behaviors were observed in (S)TEMs, after substantially reducing the electron beam current, which led to nearly non-destructive imaging of the ZSM-5 framework and the adsorbed PXs. iDPC-STEM helped reveal the local structures of ZSM-5 due to the high-contrast imaging of light O elements during in situ heating experiments, by which the temporal changes of channel geometry could be monitored. These results help the understanding of the surface terminations and interfaces of nanosized ZSM-5 catalysts and the investigation of the host-guest interactions in the frameworks, which are of great significance for the study of the physical and chemical properties of reactants and products during diverse catalytic reactions.

A variety of STEM imaging techniques and supplementary simulation methods have been summarized to exemplify their potential in revealing atomic resolution structural information on ceramic and glass materials. In the absence of elemental

analysis, simulation techniques can be conducted to compound the imaging observations. Whilst HAADF-STEM requires high beam current, iDPC-STEM can be used to image lighter elements alongside higher elements using low dose conditions and hence retain the structural integrity of a beam-sensitive sample. Alongside and beyond obtaining structural composition via STEM imaging, direct quantitative analysis can be carried out via EDX and EELS in the TEM, providing information on elemental arrangement in the samples on the atomic level.

Principles of Energy Dispersive X-Ray (EDX) spectroscopy

In EDX spectroscopy, signals from X-rays indicated as red dotted arrow in Fig. 1(a), are collected. Fig. 10(a) shows a schematic of the EDX set up in the TEM with respect to the specimen. Apart from the characteristic fluorescence peaks of the elements in the sample, Coherent Bremsstrahlung (CB) peaks (or breaking radiation as directly translated from German) are part of the EDX spectrum in Fig. 10(b). These CB peaks are generated as a result of Coulomb interactions between electrons and regularly spaced nuclei in thin crystalline specimen.

Conventional EDX detector setups allow for side-entry detectors close to the TEM specimen. To increase the signal reaching the detector a common solution is to tilt the sample towards the EDX detector. In more novel instruments, four-quadrant detectors are available (see Fig. 1(a)) and integrated in the objective lens system to improve the signal to noise ratio.

For quantification of EDX measurements, commercial software packages are available, which enable extraction and quantification of the intensities of X-ray peaks, arising from the relaxation of electrons into lower energy orbitals (after excitation into higher orbitals), i.e., the K, L, M, N and O shells of the chemical elements in the sample, and assigning the respective elements by comparison with established standard spectra (e.g., from Cu or Si). With this software, spectra are automatically saved and corrected with respect to effects impacting on these (e.g., geometry factors, and detector dead times), and are quantified by using the K-factors of the respective elements ($K = \text{number of atoms of the element/measured X-ray counts}$), which need to be known. Alternatively, registered relative K-factors, e.g., K_{Asi} (established by relating the K-factor of element A (i.e., K_A) to that of a standard element, e.g., Si (i.e., K_{Si})) can be used. For a sample with two elements, the concentrations of these elements can be found by applying the equation, $C_A/C_B = (K_{\text{Asi}}/K_{\text{Bsi}}) I_A/I_B$, where $C_A + C_B = 1$. Here C_A and C_B are the relative concentrations of elements A and B and I_A and I_B , their EDX intensities (i.e., the measured EDX counts). This process can also be employed in quantification of samples containing a number of unknown elements.

In order to obtain elemental maps of desired sample areas, EDX must be carried out in STEM imaging mode, where at each scan (pixel) position, an EDX spectrum is taken. Fig. 11 shows results of elemental mapping of a metal on graphene with near atomic sensitivity and resolution (images of Fig. 11 were obtained by the group of the author).

Fig. 11(a) is an atomic resolution HAADF-STEM image of graphene, with the brighter white dots (higher Z) representing Ti atoms at the edge of a hole (black area) in the graphene sheet. The light gray patches are C and O contamination with additional aggregates of Ti atoms. This is supported by the EDX map in Fig. 11(b), showing a uniform distribution of the C atoms in the graphene monolayer sheet as thinly spread light blue dots. Enhancement in the density of C atoms (light blue contrast) can be seen in the typical carbon contamination patches (Fig. 11(a) and (b) – top left), which appear brighter in the HAADF-STEM image, as they enhance the thickness and thus the number of C atoms in the layer, which also contain O atom clusters (dark blue) and Ti atoms (red). A couple of red dots (Ti atoms) can also be seen near the edge of the hole in Fig. 11(b), which correspond to the white dots in Fig. 11(a). Although Fig. 11(a) and (b) are

Fig. 10 (a) Schematic of the interface between the EDX detector and the Analytical Electron Microscopy (AEM) stage, showing how the detector can ‘see’ undesired X-rays other than from the specimen. The desired collection angle Ω , and the “take-off” angle α , i.e., the angle between the central beam direction towards the detector and its projection onto the specimen surface, are also shown. (b) Features an X-ray spectrum of copper (Cu), showing the characteristic fluorescence peaks (CuL , $\text{CuK}\alpha$, $\text{CuK}\beta$) of elements present in the sample, as well as Coherent Bremsstrahlung (CB) peaks. Fig. 11 (a) High resolution HAADF-STEM image of graphene, with Ti atom deposition (white dots and clumps). The black area is a hole in the graphene sheet and the light gray patches are contamination. (b) EDX map of the image in (a), showing the different elements in corresponding colors. (c) EDX spectrum taken over the entire area in (a) detailing the detection of C, O, Ti, Cu and Si in the sample. Images are original work from the research group of the author and also in reference. Reproduced from Withers, P.J., 2012. 3-D materials characterization over a range of time and length scales. *Advanced Materials & Processes* 170, 28–32.

of the same area, the reason why there appear to be slight changes in the topography is that the measurements were taken in a time sequence of several seconds and the sample might have drifted in that time. Furthermore, electron beam interaction might have caused slight changes, on the sub nm-scale, in the contamination distribution at the hole's edge, accounting for the minute differences in the topography in Fig. 11(a) and (b). Fig. 11(c) is an EDX spectrum taken over the entire area in 11a, giving proof of the elements seen in the EDX map in Fig. 11(b). EDX spectra as in Fig. 11(c), which do not require high resolution mapping but are needed to confirm the existence or presence of certain elements, can be conducted in conventional TEM mode as a simple and quick method of verifying elemental composition.

Another example of how EDX mapping can reveal detailed elemental information about a sample is shown in Fig. 12, where particle precipitation in metal doped CeO_2 is studied. In situ thermal treatment and ion irradiation techniques are used to emulate the irradiation of fuels, in order to predict the fuel performance of the material and potentially improve fuel design and operations (Jiang *et al.*, 2019). It was previously found that metallic particles formed in oxide fuels, e.g., UO_2 , during neutron irradiation,

Fig. 12 (a) HAADF-STEM micrograph and STEM – EDS maps of (b) cerium, (c) oxygen, (d) molybdenum, (e) ruthenium, (f) rhodium, (g) palladium and (h) rhenium near the surface (irradiated) of a metal-doped CeO_2 film on Yttria Stabilized Zirconia (YSZ) irradiated with 90 keV He^+ ions to a fluence of $4 \times 10^{17} \text{ He}^+ \text{ cm}^{-2}$, after annealing at 1373K. Figure adapted from reference Jiang, W., Conroy, M.A., Kruska, K., *et al.*, 2019. In situ study of particle precipitation in metal-doped CeO_2 during thermal treatment and ion irradiation for emulation of irradiating fuels. *Journal of Physical Chemistry C* 123, 2591–2601.

which has an adverse impact on fuel performance. In this study, precipitation of Mo-dominant β -phase particles in polycrystalline CeO_2 (a surrogate for UO_2) films doped with Mo, Pd, Rh, Ru, and Re (surrogates for Tc) is reported. *In situ* heating experiments were conducted in HAADF-STEM imaging mode which indicated that particle precipitation starts at $\sim 1073\text{K}$ with limited particle growth to $\sim 10\text{ nm}$. While particle concentration increases with increasing temperature, particle size remains largely unchanged up to 1273K . There is a dramatic change in the microstructure following vacuum annealing at 1373K (Fig. 12), likely due to phase transition of reduced CeO_2 . Also at 1373K particles grow up to 75 nm or larger with distinctive facets. The particles are predominantly composed of Mo (Fig. 12(d)) with a body-centered cubic structure (β phase). An oxide layer was observed after storage at ambient conditions (Fig. 12(c)).

The maps extracted from EDX measurements in Fig. 12 show that simultaneous detection of low and high Z-elements is possible, and the comparison of the signal intensities in the EDX maps in Fig. 12(b) and (c) with those in Fig. 12(c) – (f) directly confirms that the bulk of the sample consists of CeO_2 and that Ru, Rh, Pd and Re form a dense distribution of very small particles, whilst Mo particles are significantly larger and less densely distributed.

EDX spectroscopy, can be carried out down to atomic resolution with the aid of specialized software and averaging methods. The resolution of elemental maps in STEM is jointly dependent on stepping the sharply focused electron probe in a precise raster, on collecting a significant number of characteristic X-rays over time, and on avoiding damage to the sample. Fig. 13 shows aberration-corrected STEM-EDX mapping performed at 80 kV on ordered precipitates of three phases (S, β'' and Q') in aluminum (Al-Mg-(Si)-(Cu)) alloys (Wenner *et al.*, 2017). Probe and sample instability problems are handled by acquiring a series of annular dark-field (ADF) images and simultaneous EDX spectrum maps, which are aligned and non-rigidly registered after acquisition (by using software, e.g., the Smart Align (Jones *et al.*, 2015)). The summed EDX spectrum maps yield elemental maps of Al, Mg, Si, and

Fig. 13 Symmetry-averaged ADF and EDX images for three precipitates (S, β'' and Q' phases) in Al-Mg-(Si)-(Cu) alloys. EELS images from β'' are shown for comparison in column 3. All images are spatially averaged, and S and β'' are 2-fold rotation averaged, while Q' is 6-fold averaged. A common scale bar of 1 nm is given in the upper left corner. Color codes in the last two rows: blue = Al, purple = Mg, green = Si, red = Cu. In the atomic models, filled and empty circles, representing atoms at the 0 and the $1/2$ position (respectively) along the z-axis direction, are separated by $a_{\text{Al}}/2 = 202\text{ pm}$ in the paper normal direction. Reproduced from Wenner, S., Jones, L., Marioara, C.D., Holmestad, R., 2017. Atomic-resolution chemical mapping of ordered precipitates in Al alloys using energy-dispersive X-ray spectroscopy. *Micron* 96, 103–111.

Cu, with sufficient resolution and signal-to-noise ratio to determine the elemental species of each atomic column in a periodic structure (Fig. 13 rows 2 – 5), and in some cases the species of single atomic columns. Column 3 presents images acquired from EELS mapping of a β'' phase particle for comparison, showing equivalent analogies.

To obtain atomically resolved images and elemental maps, if necessary, small corrections of stage position, focus and probe astigmatism, must be made between acquisition of the individual frames, i.e., after every ADF-STEM image and EDX map acquisition. Small mis-registrations between frames, and non-linear scan distortions within frames, are then corrected in post-processing, and probe offsets from the ADF images are used to correct the corresponding EDX spectrum maps before summing these together. If the crystal structures have translational or rotational symmetry, then images and spectral maps can also be averaged by summing up images that are translationally shifted or rotated. Symmetry averaging procedures have also been applied to the measurements, from which the atomic-resolution EDX maps of nanometer-sized precipitate structures in the aluminum alloys in Fig. 13 were created. Although the example in Fig. 13 is from an alloy, it was chosen as a very good example of this atomic scale analytical imaging capability. This is also possible for ceramic materials. The images in column 3 relate to EELS analysis rather than EDX analysis. Further examples of EELS analysis are given in the following section in Fig. 18(b).

Principles of Electron Energy Loss Spectroscopy (EELS) and Energy Filtered Transmission Electron Microscopy (EFTEM)

EELS is an absorption spectroscopy technique, in which the signals indicated by the blue arrows in Fig. 1(a), are collected. The inelastically scattered, transmitted electron beam, having lost energy, proceeds through a magnetic prism, which bends the beam, and its trajectory is dependent on its energy (see schematics in Fig. 14 for details of the EELS acquisition procedure). An aperture, which can be shifted, then selects a specific energy range of the transmitted beam which enters the detector. An energy filtered TEM (EFTEM) image, i.e., taken with electrons with a specific energy loss, can then be obtained. An alternative collection method allows the beam in its entirety to be detected on a CCD camera, where each pixel detects a different energy of the beam, because, due to its different energies, it impinges at specific pixels on the camera. Spectra can then be constructed by extracting the beam intensity along a line of pixels of the detector. This can also be done in scanning mode, i.e., in each position on a raster, when the beam is scanned across a sample region in STEM imaging mode (STEM-EELS).

The energy loss region in the spectra to be acquired depends on the magnetic field strength applied to the prism (causing different deflection angles of the incoming electron beam). EELS spectra consist of a “zero-loss” peak, i.e., the undeviated beam

Fig. 14 (a) & (b) Sketches of the electron beam path through the EELS spectrometer; after having penetrated through the sample the beam passes through a magnetic prism. Depending on its energy, it is bent over many angles. In (a) the gray beam with zero-loss energy and in (b) the blue beam having lost energy, is selected by an aperture (orange) to pass through to the CCD camera. (c) Detailed schematics of the energy loss detection procedure. After passing through the prism and lenses, the beams is collected on an Yttrium Aluminum Garnet (YAG) scintillator/detector coupled with a thermoelectrically cooled (TE) semiconductor diode array. Q = quadrupole, S = sextupole. Reproduced from Williams, D.B., Carter, C.B., 1996. Transmission Electron Microscopy. Boston, MA: Springer US.

Fig. 15 EELS spectrum of aluminum (blue) and carbon (red), showing the zero-loss regions (with plasmon peaks), and the core-loss regions with Al and C K-shell absorption edges; due to the strong decrease in intensity of the core-loss edges the intensity of the graph in this energy region has been enlarged by 1000x for the Al, and by 500x for the C spectrum. The inset in the red dashed frame shows an enlarged part of EELS spectra in the low-loss region (band gap and plasmon) regime from which information on the materials bandstructure can be obtained. The spectra are of pristine and metal deposited graphene, revealing changes/enhancement of the intensity in the π -plasmon region around 3 eV (potentially leading to UV emission) in the metal deposited samples. The spectra in this figure were obtained by the group of the author; the low loss EEL spectra of graphene are adapted from Bangert, U., Pierce, W., Boothroyd, C., Pan, C.T., Gwilliam, R., 2016. Collective electronic excitations in the ultra violet regime in 2-D and 1-D carbon nanostructures achieved by the addition of foreign atoms. *Scientific Reports* 6, 1–10.

(Fig. 1(a)), a “low-loss” region due to electrons having lost energy by exciting phonons, interband (e.g., valence to conduction band) transitions or plasmons, and a “core-loss” region, due to electrons, having lost energy by exciting transitions in the K, L, M shell, etc., in the sample (Williams and Carter, 1996; Egerton, 2011). Fig. 15 shows EELS spectra of aluminum and carbon, with the mentioned transitions ascribed to the energy loss peaks. EELS can reveal the elemental nature of individual atoms (see Fig. 18). In TEM instruments equipped with a monochromator, enabling high energy resolution, EELS spectra acquired in the low-loss regime can provide information on electronic bandstructure properties (bandgaps, excitons, plasmons) complementing optical and electronic measurements. (Egerton, 2011).

Fig. 16 (a) EELS spectrum imaging carried out by the electron beam being scanned in a pre-defined raster, and in each pixel (x,y) an EELS spectrum is acquired, whose intensity is displayed along the energy (E) axis. (b) Spectrum image displayed as a 4D data array, including x, y, E and intensity. An energy ‘slice’, i.e. x,y positions at a constant energy is indicated in orange. (c) Intensity in the energy “slice” at 401 eV (nitrogen K-edge) in each x,y pixel position displayed on the “temperature scale”, to show the distribution of nitrogen in the tip of a nitrogen and boron doped carbon nanotube (spectra of the latter are not shown here). The nitrogen is incorporated at the surface of the tube, forming a shell. The image on the right is a BF STEM image of the nanotube. Sketches and images are original work obtained by the group of the author; the images in (c) are also published in reference Blank, V.D., Seepujak, A., Polyakov, E.V., *et al.*, 2009. Growth and characterisation of BNC nanostructures. *Carbon* 47, 3167–3174.

Fig. 17 Energy filtered transmission electron microscopy (EFTEM) images of a metal nitride; the electron beam energies, with which the Carbon, Nitrogen and Oxygen maps were taken are the ones of the core loss energies of the respective elements. The left-most image is taken with the original electron beam energy, i.e., is a TEM image. The right-most image is the overlay of the three differently colored elemental maps (Carbon, Nitrogen and Oxygen) and the zero-loss map. Original work from the author's research group.

The energy resolution in EELS is usually defined by the half width full maximum (HWHM) of the zero loss peak (ZLP), however, its tail, whose drop to the zero level extends over several eV (in uncorrected TEMs), also has a major impact. Energy losses in this energy regime, arising from interband transition as well as from photonic and phononic excitations, have very low intensities compared to, and are superimposed on, the ZLP tail. The ZLP intensity therefore needs to be subtracted from the energy loss spectrum, and in order to do this the shape of the ZLP tail needs to be precisely known, so that it can be fitted by a function. Due to the high intensity of the ZLP tail compared to the loss events in this (few eV) energy region, the extraction of transitions in the low loss regime revealing the material's bandstructure is very restricted, and often not possible. The use of a monochromator helps to reduce the FWHM of the ZLP from several 100 to 10 s of meV, resulting in the same resolution (10 s of meV) of the spectrum features (see example [Fig. 21](#)). This also results in the drop of its tail over only several 10 s of meV. Hence low loss events in this energy regime (phonons) can directly be monitored with high spatial (near atomic) resolution.

EELS acquisition can be carried out in various ways. In STEM spectrum imaging mode, an EELS spectrum is taken at every scan position of the beam on the sample, across the sample region selected (EEL Spectrum Imaging). This leads to a 4D data stack (x, y, E and intensity; see [Fig. 16\(a\)](#) and [\(b\)](#)), from which spectra in individual positions/pixels (along the energy axis direction), can be extracted with a position accuracy down to the atomic level. The 4D data stack can also be sliced at certain energies across the entire acquisition area, leading to a map of a specific energy loss of this area (see [Fig. 16\(c\)](#)) ([Blank et al., 2009](#)).

One of the most commonly used resources for electron microscopists engaging in EELS measurements is the EELS atlas (See Relevant Website section) which provides standard elemental EELS spectra of common materials ([Gatan, 2020a](#)). The "atlas" provides expected edge energies for elemental materials and predicted energy shifts. It is available in book format where each spectrum is displayed, in a quick guide that is commonly found in most EELS microscopy units and more recently as an app available on Android and Apple devices.

EELS can also be carried out in energy filtered TEM (EFTEM) mode. In this case the EELS aperture is positioned in a place to only collect electrons of a certain energy to form an image. If the aperture, which selects the direction (and thus energy) of the electron beam after having gone through the magnetic prism (see [Fig. 14](#)) is shifted in subsequent image acquisitions, a 4D stack can be acquired of images with different energies like in the Spectrum Imaging (SI) mode (see [Fig. 16](#)). To obtain individual EELS spectra, intensities along the energy axis in the 4D stack must be extracted at a certain position.

[Fig. 17](#) shows EFTEM images of a metal nitride sample acquired with the zero-loss energy signal (left), and energies of the core-loss energies for C, N, and O K-edge excitations (middle three images). The right-most image is an overlay of the elemental maps, and the TEM image. Nitrogen deficient pockets in the grain boundaries of the material can be identified, arising from carbon and oxygen enriched regions in these boundaries. Very thin films of carbon can be seen at all grain boundaries in the carbon map, whereas oxygen is present at higher levels and is also present in triple point regions.

Applications of High Spatially and Energy Resolved EELS

[Fig. 18](#) shows the power of EEL Spectrum Imaging with regards to spatial resolution. Shown in [Fig. 18\(a\)](#) and [\(b\)](#) (left most images) are atomic resolution images of an epitaxial double perovskite $\text{La}_2\text{CoMnO}_6$ (LCMO) thin film acquired via atomic resolution ADF-STEM and HAADF-STEM, respectively. The images following to the right of the ADF image in [Fig. 18\(a\)](#) are maps of intensities of specific energy losses of the electron beam, due to core electron excitations in Co, Mn and La atoms. These maps are extracted from EEL spectrum images and reveal elemental nature and composition on the atomic level. The color maps, constructed by overlaying the Co, Mn and La maps, demonstrate an ordered Co/Mn cation arrangement. For comparison, maps of the intensities of X-rays excited in, and emitted from, Co, Mn and La atoms due to the electron beam, are shown in [Fig. 18\(b\)](#) (to the right of the HAADF image). As with EELS mapping, EDX mapping can also be carried with atomic resolution, and results from both analytical techniques show very good agreement.

EELS studies have proven to have far-reaching implications for the safe use of nuclear materials by revealing the behavior of oxygen in uranium oxide ([Spurgeon et al., 2019](#)). The key finding is that excess oxygen from the environment can be incorporated at far greater levels than previously thought, while still preserving the nominal cubic crystal structure of the widely used nuclear fuel, UO_2 . This insight, enabled by atomic resolution EELS and theoretical calculations, allows the development of better, more reliable models for nuclear waste

Fig. 18 (a) Atomic resolution ADF image and the corresponding EEL Spectrum Imaging maps of a $\text{La}_2\text{CoMnO}_6$ (LCMO) thin film; the chemical elemental maps are shown in grayscale. The color maps with Co (green), Mn (red) and La (blue) demonstrate the Co/Mn cation arrangement. (b) Atomic resolution HAADF image shown in grayscale and the corresponding EDX elemental maps shown in the colors assigned to the elements as in (a). The overlaid colourmaps again demonstrate the Co/Mn cation arrangement. Figs. (a) and (b) demonstrate a good agreement between the data acquired from atomic resolution EELS and EDX. Adapted from reference Egoavil, R., Hühn, S., Jungbauer, M., *et al.*, 2015. Phase problem in the B-site ordering of $\text{La}_2\text{CoMnO}_6$: Impact on structure and magnetism. *Nanoscale* 7, 9835–9843.

storage and disposal. As for safe usage, the storage and disposal of actinide oxides in the nuclear fuel cycle and understanding of the O-related defects is important; their oxidation state influences fuel lifetimes, stability, and the contamination of groundwater. Aberration corrected HAADF-STEM and EELS can resolve changes in the local oxygen defect environment in UO_{2+x} surfaces. Atomically resolved STEM-EELS mapping in Fig. 19 reveals uranium oxidation states resulting from oxygen defects, i.e., local O-interstitials, through changes in the fine structure of the oxygen core-loss EELS edge in the spectra in Fig. 19(c) and (e), giving information on the mechanisms for uranium oxidation on the atomic level. (Experimental results were supported by first-principles calculations (Spurgeon *et al.*, 2019)).

Fig. 19(a) shows a composition map of the U-M_{4,5} edge collected at the un-oxidized [111] surface, illustrating compositional uniformity and crystallinity of the sample up to its top monolayer. Fig. 19(b) and (c) show the O-K edge spectra extracted from a map of the [111] surface region, progressing from the topmost layer of the crystal to its bulk. The colors in Fig. 19(b) (and also Fig. 19(d)) indicate the O-K edge intensity, and the spectra in Fig. 19(c) and (e) are from the entire area of the respective boxes, and not just from individual atomic positions, so as to provide a sum of spectra of a number of atoms, leading to higher intensity and, therefore, better statistics. The O-K edge displays two sharp peaks at 533 and 538.75 eV, followed by a shoulder at 543.25 eV and two broader features at 553 and 566 eV. There is little variation upon moving from the surface (Fig. 19(b) - spectrum 1) to the bulk (Fig. 19(b) - spectrum 7). In comparison, O-K edge measurements of the oxidized [001] surface, shown in Fig. 19(d) and (e), exhibit markedly different behavior. The overall bulk spectrum 7 is quite similar to that of the [111] sample, with a minor change in the ratio of the two sharp peaks at lower energy loss, whereas, moving closer to the sample surface, there is a redistribution of spectral features that coincides with the presence of the surface contrast band (Fig. 19(f) and (g) - spectra 1–4). These features are highlighted in the difference spectra in Fig. 19(f) and (g), where the emergence of a distinct shoulder at 530.5 eV (feature 1), changes the ratio of the two dominant peaks (features 2 and 4), and an increase in the minimum at 535.5 eV (feature 3) can be seen, as well as the emergence of a broad peak at 548 eV (feature 5). Collectively these results suggest the possibility of distinct local structures giving rise to these spectral features in the oxidized [001]

Fig. 19 Spectroscopy of UO_2 sample surfaces. (a) STEM-EELS composition map of the U-M4,5 edge measured at the un-oxidized [111] sample surface. (b) and (c) HAADF-STEM image of the [111] surface and corresponding O-K edge spectra extracted from the numbered windows, respectively. (d) and (e) HAADF-STEM image of the oxidized [001] surface and corresponding O-K edge spectra extracted from the numbered windows, respectively. (f and g) Difference plots showing changes in spectral features relative to the bulk, marked 1–5 for the [001]- and [111]-oriented sample surfaces, respectively. Reproduced from Spurgeon, S.R., Sassi, M., Ophus, C., *et al.*, 2019. Nanoscale oxygen defect gradients in UO_{2+x} surfaces. *Proceedings of the National Academy of Sciences of the United States of America* 116, 17181–17186.

surface, arising from a large amount of excess oxygen distributed across a gradient near the sample surface due to O-interstitials (although there is no evidence for a large-scale phase transition from the fluorite structure).

The EELS investigations of the samples in **Figs. 19** and **20** demonstrate the capability of core loss EELS, when spectra are taken with high energy resolution, to provide bandstructure information via the resolved core loss edge fine structure, with spatial resolutions down to the atomic level.

Fig. 20 shows again the proficiency of assessing oxygen defects (in this example, vacancies) in bismuth oxide through EELS measurements supported by Density Functional Theory (DFT) simulations. EELS measurements of $\alpha\text{-Bi}_2\text{O}_3$ are performed on three samples obtained through different synthesis methods (nanocrystals, pellet and nanowire pellet; see images in **Fig. 20(a – c)**). Experimental acquisition of low-loss and core-loss EELS spectra (shown in **Fig. 20(d)** are core-loss spectra) combined with detailed

structural characterization and DFT simulations, enables to detect and evaluate the presence of oxygen vacancies in the samples. The DFT simulations establish the relationship between oxygen vacancy concentration and the O-K edge onset, the latter occurring steeper and at slightly higher energies in the pellets and nanowires and missing out the shoulder at the O-K edge rise in the powder. Hence, EELS spectral analysis confirms an increase in oxygen vacancies in the nanowires and the pellet sample, occupying preferably the O_{II} crystallographic site.

As described above at the beginning of this paragraph, to extract bandstructure information from absorption peaks directly in the low loss regime, high energy resolution has to be achieved by employing monochromators, reducing the FWHM of the ZLP (which determines the energy resolution), to monitor absorption events in energy regimes below 1 eV. In the following examples, bandstructure information is extracted from EELS studies in the ultra-low loss regime (Figs. 21 and 22), i.e., revealing oxygen coordination in a phase-separated aluminosilicate glass via real-space mapping of the phonon properties. These properties are different and specific for different O co-ordinations.

In monochromated instruments, EELS can be carried out with ultra-high energy resolution (down to tens of meV), revealing bandstructure information on the phononic and vibrational energy level. Fig. 21 presents STEM-EELS of real-space mapping of oxygen coordination in phase-separated aluminosilicate glass, which has implications on glass stability (Liao *et al.*, 2020). This can be revealed through an understanding of the local chemistry and structure of the glass networks particularly regarding the local structures around oxygen atoms, which are the most abundant species in oxide glasses and have impact on various macroscopic properties such as viscosity, photo-absorption, hardness, and elastic modulus. The triply bonded O in the Si – O – Al configuration is more energetically favored than Si – O – Si and Al – O – Al bonds. To establish whether and where these bonds exist in the glass, nanoscale investigations are required. With the newly developed vibrational EELS technique enabled by a monochromator (termed monochromated EELS), differently coordinated oxygens in an aluminosilicate glass ($50Al_2O_3 - 50SiO_2$) can be probed at the nanometer-scale. Rather than extracting information from the fine structure of core-loss EELS, measurements are carried out directly in the vibrational (0–200 meV low-loss) energy regime. In Fig. 21(d – e), the blue peak is associated with stretching modes of AlO_5 , the green one with stretching modes of AlO_4 , and the red peak with stretching modes of the SiO_4 group.

Identical ultra high-resolution STEM-EELS mapping, i.e. in the phononic loss regime, was carried out on the same sample to achieve the results presented in Fig. 22, here concentrating on quantifying the energy difference and the distribution of the stretching modes of SiO_4 in regions of different compositions.

An energy difference of 7 meV in the peak position of SiO_4 due to (tetrahedral) stretching, i.e. a change of the local structure, was observed between the Al-rich phase and Si-rich phase indexed by white and black dashed circles in Fig. 22(b). The origin of the peak shift in the SiO_4 stretching mode is associated with a change of the Si – O bond length, although one cannot determine whether the shift originated from the Si – O bond or Al – O bond due to the overlapping of two correlations. In the amorphous

Fig. 22 Vibrational mode mapping of SiO₄ asymmetric stretching modes. (a) Mapping of the SiO₄ peak position obtained from profile fitting. The size of each pixel is 1.4 nm × 1.4 nm. A peak shift of around 10 meV is observed in the black and white circled regions. (b) HAADF-STEM image of the mapped areas. Black and white circled regions correspond to the Al- and Si-rich regions. (c) Distribution of the fitted peak positions. (d) calculated phonon DOS of the Al₂SiO₅ structure, where O atoms are mainly ¹³O. The band for the SiO₄ stretching mode is located at lower energy than that of amorphous SiO₂ (indicated by the black arrow), which is the origin of the peak shifts observed in (a). Reproduced from Liao, K., Haruta, M., Masuno, A., *et al.*, 2020. Real-space mapping of oxygen coordination in phase-separated aluminosilicate glass: Implication for glass stability. *ACS Applied Nano Materials* 3, 5053–5060.

SiO₂, all O atoms are ¹²O, as known from random network theory, whereas O atoms are favored to form a triply coordinated kyanite structure, bonded with two Al and one Si. The simulated result, based on density functional theory (DFT) calculations, is shown in Fig. 22(d). The band corresponding to the SiO₄ stretching mode undergoes a negative energy shift in the Al₂SiO₅ structure in combination with an increase in the Si–O bond length. ¹³O connected with two Al and one Si possesses a higher residual charge than ¹²O at the Si–O–Si bond, possibly leading to the formation of a weaker covalent bond between Si and ¹³O. Weak bonds possess longer bond length and result in the lower stretching frequency (leading to the downwards shift). The distribution of ¹³O can serve as a map of local glass stability, as the ¹³O fraction in the melt is regarded as a proxy of losing glass-forming ability. So, the local coordination change between ¹²O and ¹³O is resolved by the peak shift of the Si–O stretching mode. The observations confirm that the ¹³O is mainly present in the high Al content environment. This finding elucidates a long-standing mystery in glass science and gives insight into the correlation between the atomic short-range orders and nanostructures, which, on the meV energy and highly spatially resolved level, can only be achieved via monochromated STEM low-loss EELS.

Conclusion and Outlook

Analytical TEM of ceramics and glasses has proven essential in gaining an understanding of their properties on a highly spatially and energy resolved level, i.e., by revealing positions and elemental nature of atoms, as well as their bonding states, which is crucial information for targeted tailoring of these materials regarding their important universal applications. The literature reviewed in this chapter reveals highlights of information provided by employing these TEM methods. In particular, STEM-EELS has been used for real-space mapping of the oxidation state and coordination of oxygen atoms, which, being the most abundant elements in oxide glasses, have impact on various macroscopic properties such as viscosity, photo-absorption, hardness, stability and elastic modulus. High resolution HAADF STEM also revealed fracturing mechanisms in ceramics. Moreover, ion irradiation and in situ heating TEM experiments (e.g., of CeO₂, as surrogate for UO₂, to emulate irradiation of fuels, in order to predict the fuel performance) have shown particle precipitation, which has an adverse effect on oxide fuel performance.

Advancements in TEM, having led to ultra-high spatial and spectroscopic resolution, will result in increasing future use of this characterization technique to provide insight into the correlation between materials' macroscopic properties/functionalities and individual atom arrangements and dynamics giving rise to these. Having predominantly been used for investigations of inorganic materials in the past, TEM is now also progressively employed for investigations of amorphous and crystalline organic materials. This achievement is due to developments of low voltage TEM and ultra-sensitive detection equipment, reducing electron beam damage effects in beam-sensitive materials. A further ground-breaking development is in-situ TEM, by which observations of the structural behavior, down to the atomic level, can be made in gaseous and liquid conditions, as well as under heating, cooling, biasing and straining. This is especially beneficial for observing and understanding the effects of external and environmental conditions on materials' behavior regarding impacts on their functionalities. In-situ techniques have promising applications, and have already been employed, for investigations (on the nano-scale) of, e.g., the structural behavior of ceramics and glasses, under certain mechanical and chemical straining conditions, i.e., when used as materials for reinforcement and wear resistance in the construction sector, or for nuclear fuel storage.

Preface

The development of new materials in Physics, Materials Science and Chemistry in most cases requires knowledge of the crystal structure enabling the calculation of materials properties to gain a deeper understanding of how they function. Since most of the functional materials developed today are micro- or nano-crystalline, a transmission electron microscope (TEM) is the optimal tool for structural characterization. Using a TEM, it is possible to switch between imaging in direct space and diffraction in reciprocal space thus allowing large variety of experimental methods to be available. In comparison to imaging, electron diffraction experiments are less sensitive to lens aberrations and require lower electron fluxes on the sample to achieve atomic resolution data. When comparing Electron Diffraction (ED) to X-ray diffraction (XRD) methods, currently the most common approach for crystal structure solution, it is not necessary to invest time, money or resources, to grow crystals sufficiently large in size for single-crystal X-rays, or to collect a volume of microcrystals sufficient for X-ray powder diffraction, similarly for X-ray free-electron experiments, as described by [Fetzer et al. \(2021\)](#), a single parallel (ED) or convergent electron diffraction pattern (CBED) provides important information. But for ab-initio crystal structure solution, which refers to solving a new crystal structure only from electron diffraction data using no additional information, the information must be more complete and 3-dimensional electron diffraction (3D-ED) experiments are necessary.

Introduction and Brief History

Three-dimensional electron diffraction (3D-ED), while seen as a very recent breakthrough, has undergone a long development to reach the point of being more widely adopted by the electron microscopy community. Initial experiments by [Henderson and Unwin \(1975\)](#) on Bacteriorhodopsin used a combination of image and diffraction data and obtained the 3D diffraction volume at 7 Å resolution. A few years later [Hovmöller et al. \(1984\)](#), published work on niobium oxide structures, using imaging and diffraction data from low index zone axes to determine the metal positions. Apart from this being an extremely challenging and time-consuming work, a major problem needs to be described. Zone axes are where the most dynamical scattering occurs, making its use for crystal structure solution very challenging or impossible since one of its core assumptions is that the data is elastically scattered and only once, often referred to as kinematic scattering. The advent of the double conical beam-rocking system ([Vincent and Midgley, 1994](#)), otherwise known as electron beam precession, where the electron beam is rocked in a cone above the sample (scanned by beam deflectors), and then rocked in a cone in the opposite direction below the specimen (descanned by image deflectors) producing precessed electron diffraction patterns (PED) in the back focal plane of the objective lens (see [Fig. 1](#)). This tilting of the beam away from the optic axis in an angle α reduces the dynamical scattering content of the electron diffraction data. Precession around a cone allows for summing up hundreds of diffraction patterns, all differently oriented, resulting in a less dynamically modified diffraction pattern. Thus, precession data is often referred to as pseudo-kinematic diffraction. Moving the electron beam away from the zone axis during data collection causes the Ewald sphere to precess and thus integrate the reciprocal space over a wedge with the angle α as sketched in [Fig. 2](#).

In comparison to convergent beam electron diffraction (CBED), where all incident angles inside the illumination cone are available, the precessed parallel electron beam provides one incident angle resembling a hollow cone. PED can be used with a parallel illumination selecting the region of interest (ROI) see ([Fig. 1a](#)) with an selected area electron diffraction aperture (SAED) as well as by addressing it with a nano beam. The probe for nano beam electron diffraction (NBED), often referred to as nano electron diffraction (NED) or nano beam diffraction (NBD), is set up by using a small C2 aperture (CA). Thus, a significant portion of the beam is blanked and the electron flux rate is reduced. In comparison to SAED, which covers a ROI of down to 200 nm, NBED allows adaption of the probe size down to a few nanometers and is dependent upon the microscope lens system and electron source. As an example, for a lanthanum hexaboride (LaB₆) cathode to achieve a quasi-parallel beam using a TEM with a two condensor lens system and a condensor mini lens a beam diameter of ~ 14.6 nm, can be achieved with a flux ~ 250 e/Å²s, and a convergence angle ~ 0.5 mrad. With a three condensor lens system the extra control of the beam enables a smaller diameter of ~ 11.3 nm, with an increased electron flux of ~ 650 e/Å²s, and an improved convergence angle ~ 0.3 mrad, for an beam which is even closer to parallel. For a fully converged probe, the beam diameter of ~ 8.5 nm, with a flux rate ~ 800 e/Å²s and convergence angle ~ 3.6 mrad will be reached ([Plana-Ruiz, 2021](#)). ED intensities, improved by electron beam precession, can in principle be used for crystal structure solution combining several oriented zones ([Remennik et al., 2012](#); [Goujon et al., 2008](#); [Dorset, 1996](#); [Dorset et al., 2005](#)). Nevertheless, in order to derive even the positions of light atoms like H, Li, O, C, N the reciprocal space coverage needs to be as complete as possible reaching for the highest possible resolution.

The next stage in the evolution of 3D-ED methods starting in 2007 was Automated Diffraction Tomography (ADT) ([Kolb et al., 2007, 2008](#); [Mugnaioli et al., 2009](#)) which aimed to mimic the single-crystal X-ray diffraction experiment within the electron microscope by tilting the crystal over an angular range and measuring an electron diffraction pattern at a defined tilt step to get a complete coverage

Fig. 1 (a) Electron beam precession, the beam is tilted off axis in a hollow cone at angle α . (b) The electron beam precesses anti-clockwise above the sample and, clockwise below the sample to bring it back onto the optic axis.

of the reciprocal space. The diffraction experiment does not require orientation of the specimen onto a zone axis. Instead, it is possible to use the crystal as found in a random orientation. The general idea, to tilt an arbitrarily oriented crystal in the TEM under an electron beam with low convergency and record diffraction data while keeping track of the crystal's movement by means of imaging, is nowadays realized by various methods which, differ in terms of illumination mode defining the probe size or diffraction area and convergency, the applied tilt sequence and the imaging protocol for crystal tracking (Gemmi *et al.*, 2019).

The PED-ADT data collection transpires in a series of electron diffraction patterns, each step an integrated intensities pattern is recorded by oscillating the beam using precession (Mugnaioli, 2009), and the goniometer moves the crystal in defined steps (0.2° – 1°). A typical collection range for a single crystal 121° or $\pm 60^\circ$ around the zero-point of the goniometer (Fig. 2a). The range obtainable by a given crystal will depend upon the given geometric restrictions of the microscope, and the surrounding of the crystal, as described in Section “Sample Preparation and Crystal Selection”.

A few years later the method of Rotation Electron Diffraction (RED) (Zhang *et al.*, 2010) using the SAED mode was developed, where rather than applying precession the beam was stepped in very fine increments of 0.01° – 0.1° making fine slices through the reflections in order to find the reflection maximum (see Fig. 2b).

With the innovation in detectors technologies and the arrival of direct electron detectors like the Medipix 2 (Georgieva *et al.*, 2011; Llopart *et al.*, 2002), it was possible to collect diffraction data exactly analogously to single-crystal x-ray diffraction, where oscillating the crystal integrated the measured intensities, rather than moving the electron beam. As shown in Table 1, the full integration of the reciprocal space is achieved by applying either electron beam precession (PEDADT) causing a circular integration of a conical wedge, or electron beam tilt (RED) respectively continuous crystal tilt delivering a trapezoidal integration of a wedge in the direction perpendicular to the tilt axis (see Fig. 2). The high frame rates of direct detectors make it possible to continuously record electron diffraction data during the rotation of the crystal, this principle was first demonstrated by Abrahams group based on CMOS technology (Nederlof *et al.*, 2013), and the first structure was from the Gonen group (Shi *et al.*, 2013), not using a direct detector but using a TVIPS camera based on CMOS technology with high sensitivity and frame rate. Detectors used for electron diffraction experiments should have a large dynamic range and ($> 12\text{bit}$) and the detector size ($> 28\text{mm}$) minimal dead-time between frames (see Fig. 3).

Fig. 2 ADT using NED (probe size 200–20 nm, tilt step ($^{\circ}$ –0.2 $^{\circ}$)) and RED using SAED (probe size >200 nm) experimental geometry for data acquisition. Below the difference in reciprocal space integration is sketched. (a) PED (left side), (b) Beam tilt (right side). (c) and (d) Blue areas: integrated reciprocal volume sections per tilt.

In the following, automated diffraction tomography (ADT) or (PED-ADT) will be used exemplarily to inform the reader about how 3D-ED experiments are performed in transmission electron microscopes and used to solve, *ab initio*, the average crystal structure of a material from a sub-micron sized crystal.

Sample Preparation and Crystal Selection

The correct preparation of the sample and the selection of a crystal is one of the most crucial tasks to gain reliable and useful diffraction data in order to perform single crystal structure determination. As necessary for all TEM experiments the sample needs to be electron transparent. While for HR-TEM and EELS ultrathin samples are needed, the requirements for the application of 3D-ED are less demanding. Usually, a powder produced by sample grinding in an agate mortar is dispersed in a liquid, which will not alter the sample, using ultra sound and applied onto the grid by drop casting or spraying it with an ultra sound impulse onto a grid (Mugnaioli *et al.*, 2009). For ultra hard materials a tungsten carbide pestle can be used. If the quantity of the sample is very limited or it tends to adhere to the glass surface of the vial it is possible to crush the sample carefully between two blades and to apply it dry to a grid, by dipping the

Fig. 3 Rotating crystal: The crystal is continuously rotating in the electron beam, with a fast detector reading out the frames at a specified time interval.

Table 1 Comparison of three dimensional electron diffraction techniques imaging and data acquisition modes

Method	Imaging mode	Probe size	Crystal movement	Data acquisition	References
Automated diffraction tomography (ADT)	μ Probe-STEM	200–20 nm	Static crystal with 1° – 0.2° rotation steps	1° – 0.2° steps wait for data readout	(Kolb <i>et al.</i> , 2007, 2008)
Rotation electron diffraction (RED)	Selected area electron diffraction (SAED)	> 200 nm	Static crystal with 3° rotation steps	0.1° – 0.01° steps wait for data readout	(Zhang <i>et al.</i> , 2010)
Precession-assisted automated diffraction tomography (PED-ADT)	μ Probe-STEM	200–20 nm	Static crystal with 1° – 0.2° rotation steps	Integrated data 1° – 0.2° steps wait for data readout	(Mugnaioli <i>et al.</i> , 2009)
Integrated electron diffraction tomography (IEDT)	Selected area electron diffraction (SAED)	> 200 nm	Continuous rotation	step size determined by frame acquisition, 0.3 – 1°	(Nederlof <i>et al.</i> , 2013; Shi <i>et al.</i> , 2013; Gemmi <i>et al.</i> , 2015; Yonekura <i>et al.</i> , 2019)
Fast & automated diffraction tomography (FAST-ADT)	STEM nanobeam diffraction	200–20 nm	Static crystal with 1° – 0.2° rotation steps	Step-wise wait for data readout	(Plana-Ruiz <i>et al.</i> , 2020)

Fig. 4 TEM image of glass ceramic sample prepared as powder on continuous carbon support (a); STEM-DF image of glass ceramic sample prepared by ion milling (b) STEM-HAADF image of zeolite RUB-05 powder prepared on holey carbon support. Crystal positioned planar on the grid (c) and in the upright position (d).

TEM grid into the material and knocking the excess gently off the grid by tapping the tweezers holding the grid. A second, more tedious way is the preparation of thin films by ion-milling ([Fig. 4\(a\)](#) and [\(b\)](#)), described in detail by [Fetzer et al. \(2021\)](#).

Electron diffraction experiments are not as sensitive as HR-TEM to additional background originating from the carbon film. Thus, usually a continuous carbon support is used, which at the same time allows better heat and charge conduction and prevents the particles from falling through the holes in the grid. One exception is in the case of preferred orientation, where a holey carbon film is used to allow the crystals to be attached in an upright position at the rim of the holes, as shown in [Fig. 4\(c\)](#) and [\(d\)](#).

In order to acquire high quality 3D-ED data, a single crystalline grain should be selected. If the crystal is separated from other particles the probe size can be chosen freely and the tilt range is only limited by the sample holder and the microscope geometry [Fig. 4\(c\)](#). If it is attached to other crystals or embedded in a thin foil, as shown in [Fig. 4\(a\)](#) and [\(b\)](#), the tilt range is limited by the angles where the grain starts to overlap with other grains. Rotating the grid inside or outside the TEM can help to optimize the position of the crystal towards the tilt axis and change the achievable tilt range significantly.

In the special case of nano crystalline glass ceramics, thinned samples are recommended. The grains in powder samples, see [Fig. 4\(a\)](#), are usually thicker for eg., not overlapping with other grains only at the very rim, some tend to break at preferred grain boundaries and are surrounded by a thin edge of amorphous SiO_2 glass causing problems with imaging and tracking the grain over the whole tilt range. Powder samples have the advantage that the sample is not likely to be altered. In thinned samples, the grains are much more visible and less overlapped. In a corresponding powder sample can not be detected anymore. But one has to be careful to not introduce artifacts as many glass ceramics containing alkalis are beam sensitive. Another problem in multiphase systems is that one phase might be removed preferentially as it is the case for the silica glass matrix in the sample in [Fig. 4](#). In this sample Quartz crystals found in a corresponding powder sample cannot be detected in the thin foil anymore.

Fig. 5 ADT beam alignment in STEM mode with a small 10 μm C2 aperture to limit the beam size and provides higher coherency.

Illumination Mode and Imaging

In general, 3D-ED experiments apply imaging for crystal searching and tracking combined with electron diffraction for data acquisition.

The ADT experimental geometry uses a small narrow parallel beam (NED) to collect the diffraction data providing practical advantages over SAED. The illuminated area during data collection is limited to just that of the crystal which minimizes the background and improves the signal to noise ratio for the diffraction spots, which is of particular importance for low Z materials having significant amounts of inelastic scattering and therefore a high background in the measured intensities (Plana-Ruiz, 2021). It also reduces the probability of accidental collection of data from a neighboring crystal in another orientation. In addition, crystals in the surrounding area are not being damaged and for beam sensitive material a fresh part of the crystal can be selected by moving the beam over the crystal during a tilt sequence Fig. 5.

In comparison to TEM imaging, STEM does not need the lower objective lens and the image is formed from a sequentially recorded signal (Cookman and Bangert, 2021). Therefore, the electron beam can be positioned exactly on the ROI without errors caused by the aberrations of the objective lens. Another advantage of the STEM geometry is that it is easy to switch from imaging, where the beam is convergent for crystal searching and tracking, by changing a minimal number of lenses in order to defocus the beam to make it parallel for the collection of discrete reflections, referred to as the Bragg diffraction patterns. Thus, the ADT method utilizes μSTEM -HAADF imaging, where the mini lens is excited, combined with NED, where only the focus of the upper pole piece and the diffraction lens current need to be adapted to switch the modes. Agglomerated samples like glass ceramics are difficult to track, because of strong Bragg contrast changes during the tilt. Here, a HAADF detector is helpful as well and a smaller camera length should be selected for imaging. Using the NED illumination mode, where electron dose rate is reduced strongly, it is difficult to image the crystal in TEM mode. This is especially true for very thin crystals. For example the thin platelets of the zeolite sample, as shown in Fig. 4, were not visible in TEM using the NBED setting, but could be detected by the μSTEM -HAADF technique.

The ADT technique can more effectively track an individual crystal. Even if the crystal of interest is part of an agglomeration or within a matrix of material it will still be possible to collect and analyse the 3D electron diffraction from the crystal successfully.

One example is a solid polyphase material like glass ceramics, as shown in Fig. 4(b). The NED probe size should be adapted according to the projected size of the grain perpendicular the tilt axis at highest tilt angle as shown in Eq. (1).

$$\text{Grain dimension}_{x^\circ} = \text{Grain dimension}_{0^\circ} * \cos(x_{\max}^\circ) \quad (1)$$

TEM Set-up and Data Collection: Automated Diffraction Tomography (ADT)

Electron Diffraction (ED) patterns are collected by ADT while the crystal is tilted sequentially in fixed-tilt steps in the range of 1–0.2° depending on the goal of the experiment (Remennik *et al.*, 2012; Plana-Ruiz *et al.*, 2020). Whereas a standard crystal structure analysis is usually successful with 1° steps, a quantitative analysis of crystal defects, like stacking faults, demands a better scan of the reciprocal space by steps of 0.2° or lower.

Once a crystal of interest has been identified; the next step is to align the crystal to the eucentric height, ensuring it will be within the field of view during the tilt series. TEM stages are not precise enough to keep the crystal at the eucentric point, thus, the crystal will move away from its position under the beam throughout the tomographic series and crystal tracking is needed. If a crystal is large enough and separated on the grid, the goniometer sample shift, often used for SAED acquisition like for RED, can be applied to move the crystal back, but this is hardly applicable for agglomerated nanocrystals. In the ADT method the crystal can be tracked by recording an image after each tilt step and positioning the beam through a beam shift manually or according to a shift value derived from an auto-correlation of two images. In the FAST-ADT method a crystal tracking file can as well be initially set-up by acquiring images for example in 5° steps and calculating beam shift values by image correlation. By applying these values in a second tilt operation it is possible to keep diffraction conditions throughout the whole tilt series without intermediate acquisition mode changes. This approach allows the recording of ADT data sets of several crystals situated next to each other automatically in one go as well as continuous rotation of the crystal (Plana-Ruiz *et al.*, 2020). The ADT data acquisition protocol defines how often the acquisition mode is switched between imaging and diffraction. It can range from switching after every tilt step to switching one time between recording a crystal tracking file and data acquisition.

In summary, applying ADT, PED-ADT or FAST-ADT a general sequence for using μ STEM-HAADF together with NED includes (Mugnaioli *et al.*, 2009):

- Set-up a convergent beam with upper objective lens focussed on the sample for imaging recorded by HAADF.
- Set-up a parallel or quasi-parallel beam and define beam diameter for diffraction experiment recorded on CCD, CMOS, Direct Detector.
- Select an appropriate crystal and align it to eucentric height.
- Define the accessible tilt range, where the crystal will not be eclipsed by other features on the grid.
- Select a crystal tracking method, as described below.
- Start the ADT data acquisition protocol.

When precession is applied to integrate the data, after a careful alignment, as described in Plana-Ruiz *et al.* (2018) precession will be on during both the electron diffraction data collection and crystal imaging.

As demonstrated in Fig. 6 the precessing of the electron beam integrates the reciprocal volume. As the beam precesses around the hollow cone it rocks the Ewald sphere back and forth integrating a slice of reciprocal space, the width of the integration is determined by the size of the α angle, the semi-angle of the precessing beam, typically between 1° and 2°. The precession angle, α , is set to an angle such that it overlaps the integration of reciprocal space between the crystal rotation steps, meaning all reflections within the accessible reciprocal volume will be integrated. (see also Fig. 1).

The crystal is repeatedly tilted by the predetermined step size until the crystal reaches a geometric restriction of the experimental setup, which impedes any further data acquisition. This can be caused by a range of circumstances, from overlapping crystals during the tilt series, to a grid bar starting to shadow the crystal, or the goniometer reaches a physical limit. Alternatively, the crystal may show significant signs of radiation damage, typically observed by the Bragg spots at the higher resolutions being no longer observed, or being significantly weaker as the data collection progresses (Kolb *et al.*, 2010).

Data Processing and Analysis

In order to process and analyse the acquired data from a randomly orientated crystal, it is necessary to reconstruct the diffraction space volume, which will enable us to find the crystal orientation, unit cell parameters as well as define possible space groups before extracting the reflection intensities (Kolb *et al.*, 2019; Gorelik *et al.*, 2012).

The first significant difference between x-ray and electron data processing is the initial data processing step, aligning all of the diffraction patterns to a common center point, the main beam. Even an offset of a few pixels causes a blurring in the reconstructed volume. During data acquisition, switching between direct and reciprocal space induces hysteresis in the TEM magnets, leading to a small shift in SAED diffraction patterns. ADT, using NBED, shifts the beam to correct for the crystal shift during a tilt series (see section “Illumination Mode and Imaging”). If the pivot points are not accurately aligned, the beam shift will cause a remaining beam tilt and thus a significant diffraction shift. If a beam stopper was used during data acquisition, the center of the diffraction

Fig. 6 Precession reflection integration (a) the integration caused by the electron beam precession for one cut of reciprocal space, (b) A series of precession integrations taken over successive crystal tilt angles, note the overlap of integration to maximize the integration of the reciprocal volume.

patterns can be found by assigning half of the distance between Friedel pairs as the center. Usually, NBED mode allows one to work without a beam stopper and the maximum intensity within the central diffraction disk can be automatically located by assuming the highest value in the image, ignoring any hotspots, i.e., ensuring the central disk is larger than a few pixels. There are occasions when this is not the case due to large intensity variations caused by dynamical scattering or for very strong scatterers; these occasions can be checked for by manual inspection of the data. Next is to locate the spot positions on the stack of the centered diffraction patterns. The simplest way to search for the reflections is to assume any cluster with a user-defined number of members, being pixels above a user-defined threshold, as a Bragg reflection. Ideally, these clusters of pixels above the threshold should be round, or at least oval, but this is not an assumed condition of assigning the reflection spot.

The identified reflection positions are necessary for tilt axis determination, a critical step in obtaining a high-quality reconstruction of the reciprocal volume thus for cell parameter determination. In a TEM, the position of the tilt axis is mechanically defined by the goniometer axis, but the position in a diffraction pattern depends on the camera length. Inaccuracies in the diffraction lens current and the alignment for NBED with quasi-parallel illumination, when the diffraction lens excitation is used to adapt the focus of the diffraction pattern, change the camera length to an effective camera length and cause scaling and rotation of the diffraction patterns.

To search for the tilt axis a 3D reciprocal space using the determined 2D reflection positions is set up for all tilt axis values $0\text{--}180^\circ$. The difference vectors, which resemble an auto-correlation of the reciprocal space setting up a spherical surface (similar to a Wulff net), are projected into a stereographic projection as shown in Fig. 7. Each projection is analysed for its sharpness (variance) reaching a maximum for the correct tilt axis position according to a maximum of difference vector correlation (Fig. 8). An identified tilt axis angle from a coarse 1° search can be refined using a finer step size, e.g., 0.1° , $\pm 2^\circ$ around the preliminary tilt angle search, to obtain a more precise tilt axis angle (Fig. 8).

As an additional aspect, the curvature of the Ewald sphere needs to be taken into account. The gradient of the Ewald sphere curvature is small for electrons due to the large radius of the sphere. (Recall that the radius of the Ewald sphere is $1/\lambda$ with λ being between 0.019 and $0.025\text{ \AA}$ for most electron diffraction experiments). Taking account of this curvature is especially critical for the high-resolution reflections, ensuring that the spots will be inside the integration box and adequately integrated. These corrected spot positions will enable a more precise calculation of the unit cell parameters.

The unit cell determination is based on the reconstructed 3D diffraction space using 2D reflection positions, and again the difference vector space of all reflection positions is calculated. The difference vectors, which should form a lattice in difference vector space, will vary from a perfect lattice, typically by a few pixels. These inaccuracies manifest as bundles of vectors, which look like a sheaf of wheat at harvest time, rather than the vectors perfectly aligned on top of each other at a single length and orientation. Cluster analysis, in this case DBSCAN (Schlitt *et al.*, 2012), is applied to overcome the noise problem and only accept difference vectors within a pixel or two in length and a small amount of variation in angle, along with a minimum number of points in order to be considered a cluster. The centroid of this cluster is the lattice point. In applying this clustering method, we omit points from reflections from overlapping crystals, hot spots or detector defects, which have not already been taken into account.

From the clustered difference vectors, we take the three shortest non-collinear vectors to be the basis of lattice vectors. Each cluster should be an integer multiple of the shortest basis vectors. The difference vector space is not sensitive to serial or planar extinctions, but adjustments are required in the case of integral extinctions found for centered cells. The cluster routines strongly

Fig. 7 Difference vector space, and the clustering of vectors to achieve the unit cell parameters. (a) the difference vectors from one reflection to all others. (b) difference vectors from another reflection to all other reflections. (c) each reflection then accumulates a number of points the vector points to, these should form a lattice mirroring the crystal lattice. (d) all the difference vectors are then clustered by length to find the unit cell parameters, these are determined by the clustering parameters of neighborhood and number of points within the neighborhood. A dendrogram shows the graphical representation of the cutoff (e) the cluster points which satisfy the cluster analysis.

Fig. 8 Scheme of stereographic projection, stereographic projection for example SnN_2O_2 (see section “Examples”) using optimal tilt axis 42.4° and variance analysis of the tilt axis search.

depend on the parameters of the 2D peak search and fail if data is too sparse demanding a definition of the cell based on visual examination of the reciprocal space (Schlitt *et al.*, 2012). Errors in cell parameters range around 1%–2% for cell axes and 1° for angles. This can be improved by taking inaccuracies in tilt angles, tilt axis position and effective camera length into account.

With the unit cell determined and the curvature of the Ewald sphere taken into account, the positions of the Bragg peak intensities can be found in every 2D diffraction pattern and integrated, after individual background subtraction, over a user-defined area. This area should be selected to cause no overlap with neighboring integration areas, large enough to cover even strong reflections adequately and small enough not to overestimate background contribution. Since reflections have a rod-like shape in reciprocal space due to the excitation error they will be cut several times, thus, appearing in several consecutive diffraction patterns. A plot of these intensities, as provided in Fig. 9, is called a rocking curve, showing one maximum for data acquired without beam precession and two maxima if precession is applied. Lit for double peak: Palatinus *et al.* (2019). For electron diffraction data there are two main approaches to measuring the Bragg spot intensity, by analysis of the rocking curve one, fully integrate the peak shape and sum the total intensity, or take the value of the highest detected intensity within the Bragg peak assuming this to be the best approximation.

For crystal structure solution based on electron diffraction data, there are a few statistics to check before proceeding with solving the structure by for example direct methods. A first measure of the data quality is the internal R-value, which reflects the similarity of symmetrically equivalent reflections for this Laue class. Data sets with $R_{\text{int}} > 25\%$ are usually due to experimental errors or very strong dynamical effects or might indicate the choice of a wrong space group, or additional crystallographic features like twinning or diffuse scattering or simply the choice of a wrong space group. A second indicator is the isotropic Debye-Waller factor B_{iso} , which should be positive and around $2 \text{ \AA}^2$. From our experience, a negative B_{iso} is another indicator of dynamical effects or a wrong space group. Due to limitations of the tilt angle defining the size of the missing wedge (see Fig. 6 right for schematic drawing and Fig. 10, bottom right for experimental data) the number of non-accessible reflections in the reciprocal space can be large. This lack of diffraction data, which is especially problematic for space groups with low symmetry, causes uncertainties in the derived scattering density maps, thus, leading to poorly defined

Fig. 9 Diffraction pattern selected from a tilt series using ADT method (a). Rocking curve of reflection 2–3–1 as indicated by red arrow in a. The green line indicates the reflection position calculated from cell parameters (b) and for comparison Rocking curve of reflection 1–30 taken from a PED-ADT acquisition (c).

atomic positions. A crystal structure can be solved usually with a completeness of the reciprocal space of approx. 40%–60% (see sample LaPO_4 in see section eg., Fig. 14), but for a reliable refinement of atomic positions and displacement factors a high completeness ($> 80\%$) is desirable. The resolution should extend beyond $1.2 \text{ \AA}$, for many structures it will extend even out to $0.6 \text{ \AA}$ depended on the scattering power and the long-range order. However, the data used for structure solution is usually limited to $1 \text{ \AA}$ because higher-resolution reflections are usually the first to be affected by radiation damage and thus are the most prone to errors which may interfere with the assumed statistical distributions of direct methods.

To determine a set of possible space groups, the same procedure as in x-ray single-crystal approach, rules using systematic absences are applied as demonstrated. While screw axis extinctions are only visible in main zones, extinctions based on centering or glide planes, as marked in Fig. 10 with red circles, are directly visible in the 3D volume. For example, in all three views of the reconstructed volume from a PED-ADT data set (sample SnN_2O_2 ; see section “Examples”) glide planes are visible. The view down the *a* axis (top left) reveals a *c* glide plane perpendicular *b* (extinction rule $0kl: l = 2n$), the view down the *c* axis (top right) shows a *b* glide plane perpendicular *a* (extinction rule $h k 0: k = 2n$) and the view along the diagonal vector $(1-10)^*$ (middle left) exhibits a *n*-glide plane perpendicular *c*. The *n*-glide plane is directly visible in a cut of the $[001]$ zone from the reciprocal volume (middle right) showing the chess pattern like intensity distribution (extinction rule $h k 0: h + k = 2n$) as well as the area of missing reflections due to the missing wedge problem. In combination, this leads to the centrosymmetric space group Pbcn (#60). One small note of caution, systematic absences rules sometimes may be violated due to dynamical scattering. If this is the case look at the surrounding rows of reflections and compare the magnitude of the scattering to the reflections which violate the systematic absences. If they differ significantly in size and shape from the allowed diffraction spots, then it will be permissible to try this space group and argue that the symmetry breaking reflections are dynamical scattering anomalies. In Fig. 10 (bottom left) the view of the reciprocal volume from an ADT data set down the *a* axis is provided. The violations of the extinction rule $0kl: l = 2n$ of the *c* glide plane clearly visible here are lost due to the application of electron beam precession in the comparable view in Fig. 10 (top left).

There are several direct methods programs for solving crystal structures, available from the x-ray crystallography community the most popular two are SIR (Burla *et al.*, 2015) and SHELX (Sheldrick, 2008). To deploy these programs for structure solution with electron diffraction data ensure electron scattering factors (Susi *et al.*, 2019) are being used rather than x-ray scattering factors. Input the data parameters obtained from the processing of the electron diffraction patterns, a list of *hkl*s and intensities, the unit cell parameters and a space group.

When analysing the results of the direct methods software, the crystallographic R-factor for a single crystal x-ray experiment is typically only a few percent. Whereas for electron diffraction data, the dynamical scattering causes this number to increase to 20%–25%, values more akin to the structure solution of macromolecular crystallography (Reimer, 1984). Occasionally, even with high R-factors a structure can be considered as solved if there is an apparent reason for the data to be sub-optimal such as diffuse scattering from defects, or guest molecules and ions within porous materials (Jiang *et al.*, 2011).

Once a structure has been identified by direct methods, it is critical to perform structure validation, typically in the form of refinement. While kinematic refinement can work for electron crystallography data sets, we again face the issue of dynamical diffraction (Palatinus *et al.*, 2015). For data sets with low amounts of dynamical diffraction present, kinematic refinement, of the type.

Examples

Keeping the focus on oxides and especially glass ceramics this section introduces some examples of crystal structure analysis from powder and solid material. In a first step, the analysis of a high pressure modification of $\text{Sn}_2\text{N}_2\text{O}$ is used to explain the general

Fig. 10 Three-dimensional reconstruction of the reciprocal space based on PED-ADT data for sample $\text{Sn}_2\text{N}_2\text{O}$ (see section “Examples”). The diffraction volume with indicated extinct reflection rows (red circle) viewed along the a -axis (top left); the c -axis (top right); down $(-110)^*$ axis (middle left) leading to space group Pbcn . A cut of zone $[001]$ including the n -glide plane perpendicular the c -axis (middle right); a reconstructed reciprocal volume viewed down a axis from ADT data, (bottom left) for comparison with PED-ADT data (top left) view down tilt axis with a clear view of the missing wedge of 60° (bottom right).

procedure of an ADT experiment. As a second example the more challenging case of a polyphase nanocrystalline glass ceramic containing a previously unknown LaPO_4 polymorph measured with ADT will be discussed.

High Pressure Modification of $\text{Sn}_2\text{N}_2\text{O}$ (Bhat *et al.*, 2020)

The sample was synthesized in an HT-HP experiment at 20 GPa and 1200–1500°C in a large volume press from oxygen containing precursors (Li *et al.*, 2016). The resulting pellet (Fig. 11(a)) was crushed to powder. Synchrotron x-ray powder diffraction experiments (s-XRPD) revealed nicely resolved reflections of which the majority did not fit to any known crystal structure and a small quantity could be identified as remaining spinel Sn_3N_4 Fig. 11 (b). A structure solution based on XRPD data was not possible. The powdered material was dispersed in ethanol and sprayed on a carbon-coated copper grid using a modified ultra-sound sonifier (Kolb *et al.*, 2008). As shown in Fig. 11(c) a single crystal of approx. 200 nm size was selected, taking care that it sits vertically above or below the tilt axis at a sufficient distance to avoid interference from other crystals.

The accessible tilt range was identified to be $\pm 60^\circ$, defined by the limit of the tomography tilt holder used in a FEI Tecnai F30 equipped with a Super-Twin lens, and the probe size was set to 200 nm. μSTEM -HAADF images for crystal tracking were taken every 5° preliminary to diffraction data acquisition. A tracking file was stored including crystal shifts calculated by cross-correlation, which were used during subsequent ADT data acquisition with and without PED. After reconstruction of the three dimensional reciprocal space using eADT software (Kolb *et al.*, 2019) the cell parameters were derived ($a = 7.89 \text{ \AA}$, $b = 5.49 \text{ \AA}$, $c = 5.58 \text{ \AA}$, $\alpha = 89.9^\circ$, $\beta = 90.0^\circ$, $\gamma = 90.2^\circ$). The inspection of the reconstructed reciprocal space viewed in a , b and $(-110)^*$ direction reveals extinctions rules $hk0$: $k = 2n$, $h0l$: $l = 2n$, and $0kl$: $k + l = 2n$ indicating a c -glide plane perpendicular b^* and a n -glide plane perpendicular c^* . Using the derived space group Pbcn the cell parameters could be refined by Pawley-Fit on synchrotron X-ray powder diffraction data ($a = 7.8257(8) \text{ \AA}$, $b = 5.5315(5) \text{ \AA}$, $c = 5.5438(4) \text{ \AA}$) Fig. 10.

Extraction of intensity data from ADT as well as PED-ADT data was carried out with the software packages eADT and PETS for kinematical and dynamical refinement, respectively. Due to the high space group symmetry the completeness of the reciprocal space was close to 100%. The structure could be solved with both ADT and PED-ADT data based on 4529 respectively 4151 measured intensities with a limit of $0.8 \text{ \AA}$ resolution using SIR2014. Crystal structure refinement was performed using SHELX with a limit of $0.5 \text{ \AA}$ resolution covering the full width of the CCD detector. For structure refinement the quality of diffraction data is considered more important, thus, for kinematical refinement, PED-ADT data was used. In total 5176 single-crystal reflections were observed with a resolution of $0.5 \text{ \AA}$ resulting in 1046 unique reflections. After averaging, equivalent reflections in space group Pbcn . The final residual is $R_1 = 0.26$. Dynamical refinement in JANA 2006 reduced the residual further to $R_1 = 0.09$. Table 2 provides a comparison of atomic distances derived from DFT calculations in the SnN_4O_2 octahedron to the kinematic and dynamic refinement results.

High Pressure Modification of LaPO_4

A glass ceramic developed at the Fraunhofer Institute for Silicate Research ISC in Würzburg (Germany), from the SiO_2 , MgO , Al_2O_3 (MAS) system with nucleating agents Ti- and Zr-oxides as well as a series of oxide additives including La_2O_3 and P_2O_5 has been prepared by a 2-step heat treatment. Investigations by XRPD revealed several known compounds, but major reflections could not be assigned to any known phase.

As mentioned in section “Sample Preparation and Crystal Selection” the material was prepared for TEM measurement as a powder as well as a thin foil prepared by Argon thinning with a Gatan Duo Mill. The STEM-HAADF image of the thin foil in Fig. 12 exhibits crystal sizes in the range of 200 nm and below. The corresponding EDX-mapping reveals the distribution of the multiple phases present in the glass ceramic.

The grains containing Zr-Ti-O (Zr:Ti=2:1) mostly have an isometric shape and are predominantly between 20 and 40 nm in size. The La-P-O (La:P=1:1) grains have an elongated shape with lengths of up to 200 nm and a width of approx. 40nm.

For ADT experiments a probe size of 20 nm was selected, accepting that this gave a slight disk shape to the diffraction spots. The tilt range was set to $\pm 25^\circ$, which would shorten the size of the crystal along the tilt axis to 36.3 nm due to projection (see Eq. (1)).

Crystal structure analysis was successfully carried out on a series of different phases, but here the La-P-O phase will be discussed exemplarily. Cell parameters could be derived as: $a = 5.26 \text{ \AA}$, $b = 8.14 \text{ \AA}$, $c = 6.65 \text{ \AA}$, $\alpha = 90.2^\circ$, $\beta = 90.5^\circ$, $\gamma = 90.4^\circ$. For the

Fig. 11 SEM micrographs of HP-HT sample showing (a) an overview of the sample pellet after HP-HT treatment; (b) a zoom view showing crystals of varied dimensions; (c) a μSTEM -HAADF image showing the distribution of crystals on the TEM grid. The arrow indicates the crystal selected for ADT measurements and the dotted line the position of the tilt axis.

Table 2 Atomic distances of $\text{Sn}_2\text{N}_2\text{O}$ from different measurement and refinement strategies in comparison to DFT calculations. Labels of atoms as indicated in the Figure. Bond distances d (Å) with estimated standard deviations and their differences Δd (Å) from DFT and experiment

Bond	DFT	ADT (kinematic ref.)		ADT/PED (dynamic ref.)	
	d (Å)	d (Å)	Δd (Å) (DFT-exp)	d (Å)	Δd (Å) (DFT-exp)
Sn – O(a)	2.169	2.089(8)	0.080	2.110(3)	0.059
Sn – O(b)	2.343	2.323(11)	0.020	2.286(4)	0.057
Sn – N(a)	2.202	2.233(10)	– 0.031	2.190(5)	0.012
Sn – N(b)	2.174	2.107(8)	0.067	2.130(4)	0.044
Sn – N(c)	2.136	2.141(9)	– 0.005	2.124(4)	0.012
Sn – N(d)	2.223	2.183(9)	0.040	2.233(4)	0.010

metrics of the determined cell, expected error ranges of 1%–2% for distances and 1° for angles would be indicative of an orthorhombic space group. A cut of the reconstructed reciprocal space, as shown in **Fig. 13(a)**, reveals a n -glide plane ($h0l$: $h + l = 2n$) and the a diffraction pattern selected from a second data set reveals the existence of a screw axis along b ($0k0$: $k = 2n$) **Fig. 13 (b)**. These extinction rules lead to the monoclinic space group $P2_1/n$. A Pawley refinement against XRPD data provided the cell parameters $a = 5.3251$ Å, $b = 8.2549$ Å, $c = 6.7799$ Å, $\beta = 89.94^\circ$.

Intensities extracted from ADT data sets delivered only a completeness of 40%–49% due to the limited tilt range often found for thin foil experiments. As a work around, non-processed ADT data sets from different crystals were merged and used for crystal structure solution. In **Table 3** the results for two merged ADT data sets (Cr_2 and Cr_6) and one PED-ADT data set (Cr_3) are provided. Revealing a distorted baryte structure instead of the expected monazite structure type stable at ambient conditions. While the space groups of both structures are the same, the cell parameter change is mainly described by the reduction of the monoclinic angle to around 90° due to a shearing motion along the a -axis being the most compressible axis in the monazite structure. The influence of the completeness of intensity information clearly visible by the anisotropic broadening of Coulomb map residual (in yellow) is clearly visible along the missing cone direction and the resulting structural distortion is clearly visible. The LaPO_4 crystal structure is provided in **Fig. 14** together with the scattering density map.

Diffuse Scattering

In addition to the analysis of an average crystal structure 3D-ED providing a three dimensional reciprocal space allows diffuse scattering to be used to investigate defects. Stacking faults, which are 2D defects in direct space for example, will cause 1D diffuse scattering, so called streaks, in the direction perpendicular to the stacked planes. The special benefit of ADT comes into play particularly when the stacking direction does not lie perpendicular to the electron beam but parallel causing diffuse streaks along the incident beam direction. For Zeolite beta, where polytypes of Zeolite beta A and B are closely intergrown, the streaks are found perpendicular to the electron beam but for Zeolite RUB05, the streaks were not directly visible. The average structure of both materials could be solved directly from the discrete reflections, the Bragg intensities. For quantitative analysis of the diffuse scattering single zones were cut directly from the reconstructed reciprocal volume, as shown in **Fig. 15(a)** and **(b)** reveals for zeolite beta two diffraction rows which exhibit streaks whereas the third line

Fig. 16 Analysis of diffuse streaks for Zeolite RUB05 from zone [0 1 0]: experimental (a) and simulated (b) electron diffraction pattern; intensity profiles along reflection lines 20l (c) and 60l (d) as indicated in zone cuts by red rectangles: (experimental (grey line), simulated for stacking probability $p_x = 0.05$ (red line), difference (blue line); Diagram of the integrated difference function between simulated and experimental line profile as a function of the stacking probability of layer b for the line profile 20l (e) and 60l (f); HR-TEM reconstructed phase image zone [010] overlaid with polymorph I model and indicating the visible stacking sequence (g).

only contains discrete reflections indicating a coherent shift of $1/3$ of the cell. According to this a model was set up and diffraction patterns were simulated using DISCUS (Proffen and Neder, 1997). A refinement of the model underlying the simulated diffraction patterns versus the experimental data provided the probability of statistical intergrowth between Zeolite beta A and B.

Contrarily, the diffuse scattering of Zeolite RUB05, which is a layered structure and exhibits platelike crystals as shown in Fig. 4(c) and (d), was found along the electron beam direction. After the zones are cut the same principle like for Zeolite beta could be followed (Krysiak *et al.*, 2018). The simulated zone [010] is shown beside the experimental zone in Fig. 16(a) and (b). The missing wedge of the three dimensional reciprocal volume is clearly visible. The intensity distribution of the set of reflections 20l and 60l containing the majority of diffuse scattering are cut exemplarily. The extracted intensity distribution (gray line) is showing in Fig. 16(c) and (d), respectively. In this example, model building was not straightforward and additional information was necessary. The reconstructed phase image derived from HR-TEM images at different foci in Fig. 16(g) reveals the intergrowth of the solved RUB05 structure with a second polymorph by flipping polymorph I 180° around the a axis with an additional shift of $\Delta x = -0.29$. A detailed description can be found in Krysiak *et al.* (2020). Together with the experimental intensity distribution the simulated one (red line) and the difference between the two (blue line) are plotted in Fig. 16(c) and (d). Both refinements result in a stacking probability, p_x , of 0.05 provided in Fig. 16(e) and (f).

Concluding remarks

3D-ED as a promising and upcoming method uses three dimensional electron diffraction data for crystal structure analysis of unknown non-crystalline materials. The general approach of collecting non-oriented diffraction patterns through a crystal tilt, comparable to a scan of the reciprocal space, and the integration of reflections in the reciprocal space by electron beam precession or fine beam tilt reduces dynamical effects strongly, allowing the application of ab-initio structure solution methods based on kinematical diffraction theory. In particular, the methods PED-ADT and FAST-ADT, where μ STEM-HAADF imaging is applied for crystal tracking and for e.g., NBED for data acquisition, allow analyses of nanocrystals down to some tens of nanometers in agglomerated multiphase samples as found in nano-crystalline glass ceramics. Data sets with high completeness deliver atomic positions with an accuracy comparable to DFT calculations and reveals accurate information about special crystallographic features like twinning, disorder, superstructures or modulations. Combining 3D-ED with other methods available in the TEM, like EDX-Mapping or HR-TEM imaging can allow the complete crystallographic characterization of nanocrystalline glass ceramics even containing unknown phases.

Preparation of Ceramic, Glass-Ceramic and Glasses for Microstructural Examination

Michael Pomeroy, Bernal Institute, University of Limerick, Limerick, Ireland

© 2021 Elsevier Inc. All rights reserved.

Introduction

“Samples were mounted, ground and polished” is a quote which frequently, and albeit frustratingly, appears in articles which report characterization of ceramics by optical or scanning electron microscopy. Because of the lack of further detail, researchers, particularly new researchers, face the challenge of how to obtain “true microstructures” which can be correlated with material processing conditions (Chinn, 2002) and with material properties: e.g., mechanical, optical, thermal, electrical and other bulk properties (Chinn, 2002; Geels *et al.*, 2007).

It is hoped that this chapter will allow the reader to become familiar with the various stages of obtaining a true microstructure, so that with equipment and consumables vendors, they can make informed choices as to the best approaches to sectioning, mounting, planar grinding, fine grinding, polishing and etching. Prior to discussing the various processes, it is worthwhile looking at what a “True microstructure” is and how it relates to the microstructure of the volume it is supposed to represent.

Geels *et al.* (2007) and Buehler (2018a) both emphasize that a true microstructure is that which is being sought when preparing samples for microscopic investigation. The major requirement for this true microstructure is that it contains no artifacts. Arguably, an artifact free microstructure cannot be obtained, as various defects will inevitably arise. Such artifacts have been typified in ceramics by Geels *et al.* (2007) and Buehler (2018a) as follows: scratches, pull-outs, contamination, smearing, relief and edge rounding. Any of these defects, or combinations thereof, compromise the clarity of a microstructure where distinct features with dimensions in the range 0.010–100 μm should be readily resolved using a scanning electron microscope.

A near artifact free, and therefore a close to true microstructure, can be obtained with due care during grinding and polishing. However, it must be realized that the end result of careful grinding, polishing and etching is a 2D structure which is frequently used as the “signature microstructure”. This signature is frequently correlated with certain processing conditions and the various resulting properties as described above. However, the real signature microstructure is a 3D entity, and in some cases the 3D microstructure might be very poorly represented by its 2D counterpart. This is particularly the case when grains are elongated and randomly oriented. Fig. 1(a) shows, what can be taken, as a 3D representation of a specimen of silicon nitride comprising grains, which are long randomly oriented thin hexagonal rods. A typical 2D SEM micrograph of a ground, polished and plasma etched silicon nitride ceramic sample can be seen in Fig. 1(b). Clearly, the question is “What is the relationship between 2D and 3D microstructures?”. For the long randomly oriented hexagonal rods, Geels *et al.* (2007) explain that the estimation of rod size from the 2D structure leads to smaller values than expected for the 3D microstructure. Indeed, they relate that a statistical extrapolation of the 2D surface microstructure results in 80% of the grains within a given volume being shorter than expected, and thus almost equi-axed. Stereological calculations lead to more accurate descriptions of the 3D microstructure, and thus high aspect ratio silicon nitride grains with lengths generally greater than those forecast by extrapolation of the 2D view. For more equi-axed structures, the 2D and 3D microstructures are virtually the same, statistically. Thus, it is quite apparent that the “true 2D microstructure” is wholly useful for comparison sake but not necessarily reflective of the “true 3D microstructure”.

Role of microstructure in the grinding and polishing of α -sialon ceramics. *Journal of the European Ceramic Society* 23, 2351–2360.

In arriving at a “true microstructure”, it is necessary to arrive at a close to optically flat surface having sequentially ground and polished a very rough surface which was heavily scratched and damaged from initial sectioning. **Fig. 2** shows how cracks develop beneath a ground surface and that the extent of sub-surface cracking can be quite significant. The depth of such damage is dependent on the severity of the grinding, and so grinding, and indeed polishing, to arrive at a “true microstructure” involves sequentially “chipping away” at the surface with ever finer abrasive particles creating ever thinner damage layers which are associated with a true microstructure.

The Material Characteristics and Properties Affecting Choice of Techniques

In setting out to obtain a representative microstructure of a sample of a ceramic, glass ceramic or glass material, it is important to have some idea of the characteristics of the sample. An immediate thought that springs to mind, is porosity. For example, a fully dense cutting tool fabricated from a sialon material will, as it were, “Hold together” during sectioning, grinding and polishing far better than a sample of say a diesel particulate filter (DPF) which comprises a honeycombe structure with thin walls in which the filtering porosity is deliberately developed. The honeycombe/porous nature of the DPF material is best infiltrated with a low viscosity resin prior to sectioning as in fact will any sample that has open porosity (e.g., RBSN, RBSiC, thermally sprayed coatings, refractory materials).

A further factor which needs to be thought about is the area of interest in the sample. For example, if the edge of a sample is the area of interest then it may well be necessary to ensure that the mounting method and polishing method affords edge retention. That is, the edge between the sample and the material it is mounted in are in exactly the same plane after preparation. Without due care, a situation can arise where the sample stands proud of the mounting material and there is a wide rounded interface between sample and mount which is (1) difficult to image and (2) unrepresentative of the surface microstructure. Methodologies for good edge retention can involve (1) using harder mounting materials to lessen material removal rate differences between the sample and mount, (2) optimizing the relative orientation of the interface in question to the grinding/polishing direction, (3) the coating of the surface in question with an adherent hard metallic material e.g., electroless nickel.

A final factor in looking at the preparation of ceramic microstructural specimens, is the effect of material properties on grinding and polishing rates. Important properties are Young’s modulus, hardness and fracture toughness, as these control material removal rates (see [Arsecularatne et al. \(2014\)](#)) as well as depths of subsurface damage. This is exemplified in **Fig. 2** where the EQ material suffers much deeper and more substantial sub-surface damage than the EL material. Observation of the properties of the EQ and EL materials given by [Xie et al. \(2003\)](#) show the latter to have twice the toughness of the former. The hardness of the EQ material exceeds that of the EL material. Thus, tough materials develop shallower sub-surface damage.

Sectioning

Selection of Volume to be Sampled

Sectioning of a sample of ceramic or glass is carried out to obtain a specimen which is can be fully polished and, if necessary, etched ([Geels et al., 2007](#)). In making a specimen from a component or research sample of ceramic, glass ceramic or glass, certain criteria should be taken into account. For example, fired ceramic components or samples have thin surface layers which have a very different character to the interior bulk due to the surface having more opportunity to interact with the surrounding environment

(Mörtel, 1991). This is also the case for glasses and glass-ceramics where mold – surface interactions give rise to potentially different chemistries and structures extending quite a distance (1–2 mm) into the bulk material. Consideration must be given to the possibility that a sample may have preferred orientation. For example, extruded AlTi_2O_5 can demonstrate preferred orientation effects (Chen *et al.*, 2020) as can glass ceramics which surface nucleate and crystallize from the free external surface inwards (Renoirt *et al.*, 2019). Accordingly, it is very necessary to think about the relationship between the orientation of the sample and the orientation of the section. For samples where a surface coating or contaminant may be present, the sample should be taken such that any sectioning occurs with the coating/contaminant meeting the sectioning blade first (see Elssner *et al.*, 1999, Chapter 2, pages 5 and 6). In addition, orienting the surface to be cut at 45° to the blade surface will keep the coating in compression leading to a better result (Johnson *et al.*, 2015). If coatings/surface layers are particularly friable, e.g., porous coatings on metallic substrates for biomedical applications, it may well be worth impregnating the coating with a resin to maintain its integrity during sectioning. Pre-impregnation of porous materials may also be advisable for two reasons: (1) the integrity of the material is preserved during sectioning, grinding and polishing and (2) the pre-impregnated sample will not hold lubricant/coolant containing cutting debris etc. in the porous structures which may well contaminate finer polishing activities. For coatings, surface layers and surface contaminants, the use of tapered sections may assist resolution of detail. Tapering is more usually done at the mounting stage and so will be discussed there.

Preferred Sectioning Speeds and Loads

Sectioning involves the use of thin, some as thin as 150 μm , circular blades with diamond impregnated metal or resin matrix rims (see Fig. 3) operating with a lubricant/coolant. Motion is transferred by a shaft rotating in the arbor attached to the blade via flanges, friction fitted to the blade surface (Fig. 3). Blade speeds, the concentration of diamond grit in the rim, the size of the diamond grit, the nature of the rim (metal or resin) and load applied or cutting feedrate must all be balanced correctly to achieve optimum cutting rates. The selection of the settings of these parameters depends very much on the nature of the ceramic and this is generally categorized in terms of relative brittleness/toughness and hardness. For brittle relatively soft materials, resin bonded fine diamond grit wheels running at low speeds and under low loads/feedrate are preferred. For very tough and hard ceramics e.g., silicon nitride, metal bonded coarse diamond grit wheels running at high speeds under high loads are preferred (Zipperian *et al.*, 1992; Täffner *et al.*, 2004; Zipperian, 2011).

Zipperian *et al.* (1992) and Zipperian (2011) indicate that typical blade speeds range from 50 to 1000 rpm for low speed machines and up to 5000 rpm for higher speed sectioning saws. Slow speed saws are best employed for more brittle materials e.g., friable ceramics, electronic ceramics, CaF_2 , MgF_2 , glasses with cutting speeds of 500–700 rpm. For hard brittle ceramics e.g. AlN , Al_2O_3 the same authors suggest speeds of in excess of 1500 rpm up to 2500 rpm. Zipperian *et al.* (1992) and Zipperian (2011), suggest that for hard and tough ceramics such as B_4C , silicon nitride, silicon carbide, etc. wheel speeds in excess of 3500 rpm are required for sectioning. There is no doubt, given the evidence provided by Elssner *et al.* (1999), that slower speeds will result in less surface damage. These authors sectioned silicon carbide, silicon nitride and alumina using saw speeds of 200 and 3400 rpm. The comparative levels of surface damage are quite striking, with the slow speed saw yielding a much better starting surface to grind and polish and much less grain pull out. While this is typically true, Zipperian *et al.* (1992) show the significant time penalties incurred by slow speed blades with low loads compared to high speed blades with high loads. For example a 12.7 mm bar sample of B_4C could not be cut with the slow speed low load conditions employed. A similarly sized sample of silicon carbide took 19 h to cut under the same conditions while an alumina sample took 26 min. For the same samples, each was sectioned in 30 s using the high speed, high load conditions. Accordingly, it may be beneficial to use high load, high speed sectioning for hard and particularly hard and tough ceramics. It is quite often beneficial to begin a cut at low load/low speed so that the correct kerf (cut width) can be established.

Sectioning Blade: Diamond Concentration, Diamond Grit Size and Holding Matrix

The concentration and size of the grit in the sectioning blade rim are varied, as necessary, to suit tough very hard engineering ceramics, hard ceramics and sintered carbides and soft friable brittle ceramics (Buehler, 2018a). As a rule of thumb, the harder the material to be cut, the lower the concentration of diamond required in the cutting surface (Zipperian *et al.*, 1992; Geels *et al.*, 2007).

Fig. 3 Schematic of diamond cutting wheel for sectioning.

Täffner *et al.* (2004) explain that the lower the diamond concentration, the higher the stress applied to the diamond surface in contact with the ceramic surface being cut. Greater contact stresses on each operating abrasive particle lead to greater cutting rates. Clearly, higher loads also increase these contact stresses and thus induce greater cutting rates. The same of course can be said of material feedrates, since the higher the feedrate the higher the force applied to the material.

Johnson *et al.* (2015) give a table of materials and respective recommended diamond wafering blades. The table indicates that diamond loadings in the rim of the cutting wheels range from 20LC for hard tough ceramics, through 15LC and 10LC, to the lowest loading of 5LC which is for brittle, friable materials. Other manufacturers will have a similar grading of diamond grit concentrations. Grit sizes are likely to diminish in a similar way with finer grit sizes being used to section brittle, friable materials and coarser grits being used for hard/tough ceramics. Zipperian (2011) indicates that coarse diamond grits for sectioning are about 120 grit (120 μm) and fine diamond grit is typically 600 grit (26 μm).

The selection of the matrix in which the diamond particles are held is important. This is best demonstrated by the reportage of Mörtel (1991) who sectioned quartz with brass bonded and resin bonded diamond grit wheels. Whilst the resin bonded diamond cut the quartz successfully, the brass bonded diamond left a lubricating smear of brass in the cut. The resin bond allowed blunted diamond particles to be pulled out of the resin leaving a continually sharp collection of diamond particles in contact with the work piece. Elssner *et al.* (1999) indicate that the harder the material then the softer the holding matrix, indicating that hard and tough non-oxide ceramics can be sectioned using resin bonded diamond whilst oxide ceramics are frequently sectioned using metal bonded wheels. Friable, brittle ceramics are typically best sectioned with resin bonded diamond (Täffner *et al.* 2004). Clearly, a drawback of using resin bonded diamond wheels is their greater tendency to wear. The wealth of knowledge developed by companies selling cut off blades is now significant and so from a basic knowledge of what material needs to be sectioned and its properties and the background information given here, the correct selection of cut off blade can be made by the user in conjunction with a preferred supplier.

Prior to first use or after periods of use indicated by a falloff in cutting performance, it is important to dress the abrasive sectioning wheel. This bares diamond particles from the metal or resin bond and allows them to become fully effective when put into use for sectioning. Dressing sticks are clamped into position and the sectioning blade made to make a cut into it. The dressing stick is typically a porous resin material containing alumina abrasive particles. Zipperian (2011) shows clear evidence of the effect of wheel dressing on sectioning times of the same thicknesses of silicon nitride. Cutting times for one and two sections are very similar, however, for the third cut though the time taken is six times that for the previous two cuts. Following dressing, after the third section has been made, cutting times revert to those seen for the first and second cuts. Thus, it is very useful to monitor how long each section takes and to dress the diamond impregnated wheel as appropriate.

Sample Support

As already indicated, sectioning blades are extremely thin (some as thin as 150 μm), and thus fragile. In the writer's experience, blades are most likely to fail from poor anchoring or alignment of the specimen during sectioning. In general, blade failure arises by local spallation of the abrasive diamond loaded rim. Any movement whatsoever during cutting of the sample will cause the wheel, particularly its rim, to be pinched within the cut and thus induce failure. As well as blade failure, correct specimen support can prevent the fracture of a very thin section of sample at the end of the cut, leading to non-planarity prior to grinding. This is best avoided by the use of a double chuck arrangement where both sides of the cut are supported (Chinn, 2002). For porous and friable ceramic samples, sectioning is best performed using rubber pads between the jaws of the chuck and the sample and this is also a solution to preventing the development of vibration within the sample during sectioning (Zipperian, 2011). Chinn (2002) shows a selection of simple specimen holders for tube or bar, mounted samples and for making thin sections. Examination of current fixing devices shows that they are much the same with subtle variation e.g., tear drop geometries for holding mounted samples (to accommodate difference in size), irregular specimen chucks etc. For currently available chucks and specimen vices, it is best to consult materialography manufacturers (e.g., Buehler, Struers, Kemet, Presi, PACE Technologies) websites.

The orientation of the sample to the cutting wheel can alter the efficiency of cutting. The best orientation appears to be when the thinnest part of the sample is presented perpendicularly to the wheel (Fig. 4(a)). Johnson *et al.* (2015) indicate that this is the preferred arrangement for optimal cutting, drawing attention to a "door-wedging" effect (Fig. 4(b)) or lower efficiency cutting if the sample is angled in the opposite orientation (Fig. 4(c)). Note however, as indicated in Section "Selection of Volume to be

Fig. 4 Schematic diagram of preferred orientations of presentation of sample to cutting wheel: (a) optimum, (b) "door wedge" opposing blade motion more strongly, (c) lower efficiency orientation but preferred in the case of coatings surface contaminants with coating surface first contacting the blade.

Sampled", that coatings/surface layers should be oriented such that the coating is presented to the blade first, albeit at a greater angle than in Fig. 4(c).

Coolants/Lubricants

The purpose of a lubricant used during sectioning is to remove cutting debris, including degraded bond and diamond, from the cut, keep the sample, blade and cutting rim cool and provide lubrication for the blade to glide through the cut (Geels *et al.*, 2007). Coolants/lubricants can be either water- or oil-based and can be best selected in consultation with consumables suppliers. In choosing between water- or oil-based coolants, the nature of the sample should be considered. Clearly, a material, coating or surface contaminant that is water soluble or whose integrity affected by water should be sectioned using oil-based lubricants. Elssner *et al.* (1999) refers to β -alumina, CaO, MgO, magnesite as being materials affected by the use of water-based coolants. The writer has used such coolants as petroleum spirit and white spirit during the low speed sectioning of corrosion products and deposits (particularly $(K,Na)_2SO_4$ and Ca-Zn-P-S-O deposits) on both metallic and ceramic (sialon) substrates. Better oil based lubricants are on the market which will act equally as well. Correct environmental disposal protocols must be taken in disposing of coolants and these may affect the choice of lubricant/coolant.

Cleaning

Mörtel (1991), Elssner *et al.* (1999), Chinn (2002) and Geels *et al.* (2007) all very clearly state that cleaning samples after sectioning and other steps during the sectioning, grinding and polishing procedure is, arguably, as important as carrying out the steps themselves. This is because there is a significant likelihood of specimens becoming damaged by abrasives and cutting/polishing debris left as contaminants on them after each step in the preparation of a polished specimen. Such damage would of course require reworking of the specimen, with attendant time and indeed material losses. Geels *et al.* (2007) give a comprehensive analysis of methods for specimen cleaning. They also mention the importance of carrying out other measures (e.g., hand washing, equipment cleaning, minimizing dust) in order to reduce the potential of specimen damage due to contaminants.

Generally the agreed best way of specimen cleaning is to use ultrasonic agitation of a suitable detergent solution or, if the specimen contains water soluble components, a non-aqueous solvent. The ultrasonic agitation creates bubbles in the liquid that impinge on and implode on surfaces in the cleaning fluid. This process is referred to as cavitation. These impingements and implosions set up shock waves on the surfaces to be cleaned with the result that a specimen sample is gently cleaned both chemically (solution of grease etc.) and physically (scouring effect of bubbles).

Non-aqueous solvents must be selected and treated with care because of health and safety concerns. Risk is minimized if they be used under a fume hood and the correct fire-retardant is available should any untoward situation arise. Aqueous cleaning agents are usually based on highly alkaline solutions which are designed to remove oil and grease. In removing oil and grease from a cut specimen, diamond and cutting debris is removed also. 30–120 s is a suitable time for the cleaning of most specimens after sectioning and indeed grinding and polishing. For brittle, friable specimens, shorter times should be used to avoid their decrepitation by the cavitation effects referred to above. It may well be better to impregnate such sample types with a resin to "anchor" the structure and prevent the possibility of its damage during ultrasonic cleaning.

After cleaning, specimens should be rinsed with distilled or de-ionized water and dried, unless they contain water soluble phases when a solvent such as ethanol might be used for rinsing. Drying is best carried out with a fan type heater, even a hair drier! Additional information on specimen cleaning and equipment (polishing wheels etc.) is given in following sections.

Mounting

Introduction and Initial Considerations

Mounting a specimen is carried out to make the specimen more readily held, either by hand or machine, during grinding and polishing (Buehler, 2018a). Specimen sizes should be no more than 50% of the diameter of the mount and mounts should be at least 20 mm high. The writer has seen many examples of thin (10 mm high) mounts which either cannot be sufficiently well gripped by the heads of a semi-automatic grinding and polishing machine, or indeed by hand. Clearly, it is important that a specimen is not damaged during mounting (Buehler, 2018a). As well as realizing that the selection of the mounting method and material contributes greatly to quality of the finished polished microstructure. Accordingly, a holistic approach must be taken when selecting a mounting procedure. Initial considerations prior to mounting are based upon the specimen size and characteristics. These considerations go to help answer the following questions: which mounting method should be used (simple clamping, hot compression or cold casting), does the specimen need support during mounting and how that might be effected, will examination of the specimen edge be important, does the specimen need any pre-treatment before mounting e.g., pre-impregnation, will the available resins/polymers have the right characteristics as a mount for the specimen, will the hardness of the mounting material need to be augmented by the addition of hard particles, is a conductive mount needed to aid electron microscopy, if etching is required will the mount be resistant to the etchant(s) or will it need removal, etc.? Indications of the answers to these questions are given in the following sections.

Pre-Treatments Including Pre-Impregnation

It is important to have a clean dry specimen to which the mounting medium adheres very well. If this is not the case, then grinding/polishing media and fluids can become entrapped in gaps between the specimen and the mount and lead to contamination of finer polishing steps and smearing of the polished surface by fluids being drawn over the surface by surface tension effects. Cleaning methods are addressed in the previous section. Mörtel (1991) suggests drying samples for at least 1 h at 110°C to ensure that any moisture on the sample surface is removed resulting in a good mount – specimen bond. Such good mount-specimen bonding also helps good edge retention (Geels *et al.*, 2007).

For more porous materials e.g. with porosities greater than 15%, it may be useful to pre-impregnate them with a low viscosity resin (e.g., an epoxy) prior to mounting them (Chinn, 2002). This is done by holding the specimen in a vacuum chamber, evacuating the chamber to low pressure, typically 10–25 kPa and then allowing the resin to flow into a mold in which the specimen sits. Once a sufficient depth of resin covers the sample, the vacuum can be released and the vacuum chamber allowed to come up to atmospheric pressure which then “pushes” the resin into the pores of the porous ceramic (Chinn, 2002). For specimens with 5%–15% porosity, vacuum impregnation can be similarly effected. However, as this porosity level is associated both with open as well as closed pores, it may be necessary to repeat the impregnation process after planar grinding to seal the newly exposed porosity in the face being prepared for examination (Elssner *et al.*, 1999). Resins with added dyes can be obtained or made up so that prior porosity can be seen under the optical microscope if the dye fluoresces (see Brindley and Leonhardt, 1990; Elssner *et al.*, 1999; Buehler, 2018a). Simple pre-impregnation systems can be put together from a vacuum dessicator with a central port for the admission of the resin and a side port for the application of the vacuum which can be developed by a water jet pump as well as by a roughing vacuum pump. The major materialographic suppliers (Buehler, Struers, Kemet, PACE Technologies and others) can supply suitable equipment for the vacuum impregnation of several samples in the same vacuum chamber.

Better edge retention can be afforded by the application of a layer of hard nickel deposited on the specimen by electroless deposition. Of course this is not suitable if surface layers contain water soluble components as the solution in which the specimen is plated is an aqueous solution. This applied coating will support the edge during grinding and polishing. Geels *et al.* (2007) detail the composition of an electroless nickel solution and indicates a plating rate of $15 \mu\text{m h}^{-1}$ if a temperature of between 90 and 100°C is employed. Geels *et al.* (2007) state further on in their article on mounting that, because of the availability of resins and polishing procedures including semi-automatic ones, electroless nickel plating is not often necessary.

Taper Sectioning

In order to thicken a coating or surface contaminant layer for detailed microstructural examination, taper sectioning can be employed. Fig. 5 shows how a coating of thickness T is amplified to an effective thickness ET by gradually decreasing the angle α . For an $\alpha = 10^\circ$ the magnification factor is 5.8. This then makes examination of coatings or surface layers easier, although this might not be the case for electron microscopy where the beam may penetrate through the thinner parts of the coating and be backscattered from the substrate. Care should also be taken if microhardness measurements are to be taken as the thickness of the coating will vary across its effective thickness (width as it is being looked at). The simplest way to create a taper section is to glue a piece of wire at one end of a coated sample. For example, a 3 mm diameter wire glued one end of a 20 mm square specimen will give an α angle of about 8° and a magnification factor of 6.5. An excellent description of the application of the taper sectioning technique to a detailed transcolumnar analysis of EBPVD thermal barrier coatings, is given by Kelly *et al.* (2008).

Mounting Methods

Mounting in clamps

Mörtel (1991), Geels *et al.* (2007) and Buehler (2018) all refer to clamping of samples in metal fixtures as a suitable way to support and grip a specimen for subsequent grinding and polishing. Mörtel (1991) shows typical schematics of fixtures which can be used to hold wire, rod or plate samples between metal plates which can apply a suitable gripping force via screws which pull

Fig. 5 Schematic of taper sectioning, showing how a surface layer of thickness (T) = X can be extended to an effective thickness, ET by angling the surface layer toward the horizontal at different angles α .

metal plates together. He also shows how a ceramic rod can be gripped by holding it within a metallic tube with a screw applying a holding force. In general, clamping is used for larger samples and manual grinding and polishing. Advantages of clamping are: (1) it is simple to effect, given suitable machining facilities to cut, drill and tap steel plates or tubes, (2) it can be used for large specimens, (3) It can give excellent edge retention as the edge is supported by the steel clamp which is much harder than the polymers used for hot or cold mounting. Disadvantages of clamping are: (1) Clamping can cause cracking or crushing of samples or surface coatings, (2) As clamping involves potential gaps between specimen and clamp and in other areas, contamination of grinding laps and polishing can occur without sufficient cleaning between steps, (3) Polishing cloths can be damaged by sharp clamp edges and so it is advisable to bevel the clamp edges.

Hot mounting

Hot mounting, or compression mounting, involves the embedding of a specimen in a thermoplastic or thermosetting polymer under the influence of pressure and heat. Typical pressures employed are 20–30 MPa (Geels *et al.*, 2007) and are wholly sufficient to cause cracking of specimens. The writer has seen many a glass, glass ceramic or ceramic specimen ruined by the presence of a “mounting crack” at or near an area of interest which cannot be photographed for publication! Temperatures up to 200°C are employed during compression mounting (Zipperian, 2011). Available polymers for hot mounting are: acrylic, phenolic, epoxy or diallyl phthalate in powder form. The acrylic material is a thermosetting resin whilst the others are thermosets. It is the thermosetting resins which are preferred for glass and ceramic materials due to their higher hardness and wear resistance. This is particularly the case for the diallyl phthalates and epoxy resins when filled with silica fibers or glass particles (see hardness and wear data provided by Elssner *et al.*, 1999). Elssner *et al.* also indicate that the adhesion of epoxies or diallyl phthalate mounting media to the specimen is excellent giving two advantages: (1) improved edge retention and (2) negligible interface gaps reducing contamination transport to finer grinding and polishing steps. The filled resins also improve edge retention due to the increased hardness of the composite mounting medium compared to the resin alone. In addition to fillers imparting hardness, conductive fillers such as fine copper or carbon particles can be added to the mounting medium. These aid clarity of scanning electron microscope images by helping to reduce charging. Detailed characteristics of the various resins are given by Elssner *et al.* (1999), Chinn (2002), Geels *et al.* (2007) and Zipperian (2011).

Chinn (2002) and Geels *et al.* (2007) give instruction as to how the hot mounting method is carried out, and this corresponds reasonably closely to operating instructions given by equipment and mounting material manufacturers. Other useful tips are as follows: (1) While thermosetting resins must be heated and cooled under pressure, thermoplastics can be cooled without being under pressure (Buehler, 2018a). (2) Specimens should be centered within the mounting area and then a small amount of mounting powder poured around it. This anchors the specimen in the center of the mount when the requisite remaining powder is poured into the die and pressure and heat applied. (3) Economies can be made in the use of more expensive mounting resins by using a small amount around the specimen, perhaps 5–8 mm thick which is backed by a cheaper resin layer (Chinn, 2002; Geels *et al.*, 2007). Chinn also suggests using a top 2–3 mm layer of a transparent mounting material through which an identity label can be read.

Mörtel (1991) and Chinn (2002) give examples of mounting defects which are serious enough to render a mount and the sample it contains unusable for subsequent grinding and polishing. Such defects can be listed as follows: Radial splitting, Edge shrinkage, Burst bottom, Burst top, Incomplete fusion and Circumferential splitting. These authors give reasons for the creation of the defects and methods by which they can be eradicated. It is always worth discussing any such problems with powder and equipment suppliers as well as consulting the useful information of Mörtel (1991) and Chinn (2002).

Cold mounting

Cold mounting using castable resins is perhaps the best method for mounting ceramic and glass materials for examination. This is because the resulting mounts are relatively hard, adhere well to the specimen and can be sufficiently fluid to penetrate surface and linked porosity and, perhaps, most importantly, in many instances, avoids the use of pressure which may cause damage to the specimen during mounting. Three types of systems exist: (1) acrylics, (2) polyesters and (3) epoxies. Generally, epoxies are preferred for ceramic and glasses as they are hard (Zipperian, 2011) and have excellent wear resistance compared to acrylics or polyesters (Elssner *et al.*, 1999). Other reasons why epoxies are preferred for mounting ceramics and glasses are: (1) they physically adhere to specimens, precluding contamination being trapped between the specimen and the mount and improving edge retention, (2) they have low shrinkage so that the mount does not “pull away” from the specimen during curing again improving edge retention, (3) low viscosity epoxy resins can infiltrate surface depressions, cracks and porosity, allowing ready observation. As with the hot mounting resins, fillers can be added to an epoxy to improve its hardness and edge retention capability (e.g., plate like ceramic particles, ceramic particles) or conductivity (e.g., graphite or copper particles). These can be added and mixed by the researcher according to supplier instructions. As pointed out by Buehler (2018a) the viscosity of the resin/filler admixture is increased. However, the viscosity of the resin is unaffected and so it can flow into surface depressions etc. just as easily as if it were filler free.

Chinn (2002), Geels *et al.* (2007) and Zipperian (2011) all give the methodology by which castable mounting is conducted. Molds for the casting can be one part flexible silicone rubber molds, rigid two part molds where the base is detachable or ring forms which are open cylinders which are placed on a glass plate and remain as part of the mount after the resin has cured. For the two part molds and ring forms, it is best to grease contacting areas to semi-seal them such that resin leakage is negligible. As the resin is poured into the mold, the flow patterns can easily displace a specimen which is not prior secured in place. Chinn (2002) suggests the use of double sided sellotape to securely locate the specimen in the center of the mold area. The writer would prefer to fill the mold very slowly to a depth of 5 mm or so and ensure that the specimen is in the correct place before filling the mold more fully. For epoxy

resins, curing times and peak curing temperatures are dependent on the type of resin and the resin to hardener ratio. These can range from 9 h with a peak temperature of 65°C to 1 h with a peak temperature of about 160°C. Curing rates can be accelerated by preheating the resin to about 50°C before carrying out the mixing and mounting, or putting the mounts to cure in an oven at 30–40°C. However, peak curing temperatures will be increased accordingly, with the result that thermal degradation of the resulting mount is likely to arise. Curing rates can be slowed by placing curing mounts in a refrigerator. Zipperian (2011) has created a troubleshooting table for problems arising during castable resin mounting. This table covers the following problems: Lack of or partial curing of resin: Soft or gummy resins (grinding produces a matted finish), Bubbling, cracking, or yellowing of resin, Curing time takes too long, and Bubbles in resin. In addition to defining these problems, Zipperian (2011) also gives the cause of the problems and how the problems might be remedied. Incidentally, bubbles in the resin can be removed by mounting under vacuum under much the same conditions as suggested for the infiltration of porous samples (see Section “Pre-Treatments Including Pre-Impregnation”).

Post mounting operations

Post mounting operations are quite simple. They comprise the following:

- (1) Beveling the edges of the mount face: The edges of the mount face which will subsequently contact the grinding and polishing wheels should be bevelled. This improves the wear of any papers or cloths used on grinding/polishing wheels and helps to prevent them ripping. Chinn (2002) describes how this might be best done in a lathe or by grinding the edges at an angle of 45° to the mount axis on a coarse abrasive paper on a belt. An abrasive paper on a wheel may also be used.
- (2) Flattening the top faces of cast mounts: Because of the meniscus formed during the casting of resins, it is useful to flatten the resulting surface protrusions after mounting. Again this can be done in a lathe or by an abrasive belt or wheel.
- (3) Identity marking: It is always important to engrave or deeply scratch an identity into the top surface or the circumference of the mount. This identity should not only have an identifier as to the specimens reference for the individual, it should also bear some indication of the owner of the specimen. Such marking can be carried out with a small hand engraver or the sharp tip of a dentist's probe.

Grinding and Polishing

Introduction

As indicated in Section “Introduction” the method by which the “true” microstructure is arrived at involves “chipping away” at a damaged surface with ever finer abrasive particles. Fig. 6 taken from Xie *et al.* (2003) shows how sub-surface cracks develop beneath a groove and contact zone created by a sliding abrasive particle contacting a sialon ceramic surface. In addition to showing how increased material toughness limits sub-surface cracking, the schematic also shows how a potential chip is formed and what volume it can assume. The depths to which the cracks form, and thus indications of depths of material damage, diminish as finer abrasives are used. Reviewing the work of Moore and King (1980), Arsecularatne *et al.* (2014) and Yin *et al.* (2018) indicates that depths of damage due to subsurface cracking and associated strain fields are dependent on the stresses applied to abrasive particles

Fig. 6 Schematic of subsurface cracking during grinding and polishing of low toughness (EQ) and high toughness (EL) α -sialons. After Xie, Z.-H., Moon, R.J., Hoffman, M., Munroe, P., Cheng, Y.-B., 2003. Role of microstructure in the grinding and polishing of α -sialon ceramics. *Journal of the European Ceramic Society* 23, 2351–2360.

and their diameter. As might be expected, the lower the stresses and smaller the particles then the shallower the depth of surface damage, allowing the perfect microstructure to be approached. Of course, the amount of material removed by grinding and polishing steps is greater when stresses are high, and abrasive particle size large.

In addition to applied loads and abrasive size, the manner by which the abrasive interacts with the ceramic is also important. Zipperian (2011) explains that the abrasive may be fixed to or embedded in the polishing platen or lap, or it may be free to “roll” on the surface between the platen/lap and the ceramic surface being abraded. A third variant involves some abrasive particles being free to “roll” while others are fixed by undulations in the lap/platen surface. Materialographic suppliers each have their own variants of polishing platens/laps which correspond to the fixed, free rolling or semi-fixed variants. Fixed abrasives give more rapid stock removal but introduce more damage into the surface layers, thus requiring more material removal during subsequent stages. Zipperian *et al.* (1992) indicate that fixed abrasives are best used to grind electronic ceramic components with softer metallic interlayers because the fixation of the abrasive precludes it becoming embedded in the softer metallics such that the true microstructure cannot be revealed. Free and semi-free abrasives are best employed for edge-retention and porous samples (Zipperian *et al.*, 1992). In the writers experience, they also reduce the amount of grain pull out during coarse grinding. Extended fine grinding and polishing reduce pull outs to a minimum level (Elssner *et al.*, 1999).

The type of abrasive used for grinding and, indeed polishing, is of course important. Zipperian (2011) presents a table of typical abrasives and their hardnesses. Combining this useful information with the suggestion of Vander Voort (2009), that the hardness of the abrasive should be at least 1.5 times that of the material to be abraded, suggests that diamond is the only abrasive of choice for materials with hardnesses in excess of 15 GPa. For softer materials e.g., glasses, glass ceramics, silicon carbide may suffice.

Manual Grinding and Polishing

As indicated by Buehler (2018a), it is often the case that the forces developed between the specimen and the abrasive platen or lap are very high and cannot frequently be resisted to the required degree to facilitate efficient grinding. In addition, as material removal rates are typically slow for ceramics and glasses, the application of high force by hand for long periods of time is unlikely to be completed without breaks. This gives rise to the potential for specimens to become bevelled during extended manual preparation or the specimen to become non-level across its area. Such bevels preclude proper examination at a later stage as does a non-level surface.

Machine Grinding and Polishing

Machine grinding and polishing is much preferred for the preparation of ceramic specimens for microstructural analysis. Grinding and polishing machines allow specimens to be held in a rotating head, which pushes them against the abrasive platen/lap with a controlled force. The latest machines supplied by Buehler, PACE Technologies and Struers (see Fig. 7) have speed controls for the platen as well as the head holding the samples (see Fig. 8). Assessing the current machines offered by these suppliers shows a variety of wheel speeds and directions, head speeds and directions and ranges of force which can be applied to the rotating head, or individual specimens.

According to Zipperian (2011), the rate of material removal $\dot{G}$ is given by Preston's Law, $\dot{G} = k \cdot u \cdot f$, where k is Preston's constant u is the polishing velocity and f is the polishing pressure. Polishing velocities are complex depending on whether the directions of the

Fig. 8 Typical specimen holders where force is applied centrally. Taken with permission from Struers, 2020b. Available at: <https://www.struers.com/en/Products/Grinding-and-Polishing/> (accessed September 2020).

polishing platen and head holding the samples rotate in the same way (complementary-rotation) or the opposite way (contra-rotation). For the former, the relative velocity between the grinding platen and sample head is constant for all angles of rotation of the specimen holder. The actual differential velocities between the grinding platen and the sample head depends on the speed settings for them. For equal speed settings of 200 rpm, Zipperian (2011) shows a differential velocity of 1.05 m s^{-1} (2500 in min^{-1}). When the rotation is contra in direction the differential velocities vary considerably with angle of rotation of the specimen holder. With the platen rotating at 200 rpm and the sample head at -200 rpm , the differential velocities are 3.2 , 1.05 , 2.1 and 1.05 m s^{-1} for rotational angles of 0 , 90 , 180 and 270° respectively. This means that the selection of contra or complimentary rotations will have an effect on the grinding rates of specimens.

Zipperian (2011) indicates that the contra rotation mode gives rise to the highest material removal rates, particularly when the sample head rotates more slowly than the grinding platen. As already indicated, for equal but opposite rotation speeds for platen and head, the maximum relative velocity is at an angle of 0° ; i.e., when the specimen is at the outer diameter of the platen. For a similar head speed, when the platen speed is higher this relative velocity will be even greater, as of course will material removal rates. Of course, the relative velocity at when the specimen is closest to the center of the wheel is a minimum and it can be imagined that there will be a hammer like action when specimens and platen are contra rotated (Zipperian, 2011). For complementary rotation, the lower and constant relative velocities lead to less aggressive material removal rates and subsurface damage. Zipperian (2011) draws attention to the fact that specimen flatness levels and a uniform finish across the ground surfaces are also favored by complementary rotation. Perusal of grinding conditions given by Elssner *et al.* (1999), Chinn (2002) and Zipperian (2011) and those suggested by Buehler and Struers on their websites indicate that platen speeds of between 200 and 300 rpm are employed for ceramics and glasses.

The orientations with which the specimens are oriented to the abrasive travel direction is important. According to Zipperian (2011) it is best to ensure that any specimen edges with contaminants or coatings are kept in compression. This is effected by having that edge of the specimen being the first edge to be in contact with the abrasive which then goes through the remainder of the sample (see Fig. 9). Experience has shown that a slight (10°) offset from the perpendicular gives better results than when the surface is truly perpendicular to the abrasive travel direction. Specimen orientation is also important for electronic ceramics and laminar type specimens, where it is important to ensure that the abrasive strikes any metallic interlayers or lamellae in a perpendicular manner. In the writer's experience, good edge retention and integrity of surface layers and internal interlayers is best

Fig. 9 Orientations of specimens toward abrasive travel direction (arrowed) (a) abrasive likely to tear surface coating (gray). (b) internal metal electrodes (black). Arrows represent abrasive travel direction.

achieved with contra rotation, such that material removal is most significant when specimens are nearly orthogonal to the outer diameter of the grinding or polishing platen. This is most probably because of the greater relative velocity when the specimen is at the 0° position on the grinding platen and this corresponds to the abrasive travel direction shown on Fig. 9.

Grinding pressure can be applied either to each sample individually or through the center of the specimen holder, putting an equal load on all specimens. The latter type of loading applies to the specimen holders shown in Fig. 8, where specimens are clamped in position and so can be oriented as required. In the case of individual loading, the specimens can freely rotate within a containment ring and so cannot be specifically oriented. Typical loadings for ceramic samples suggested by Elssner *et al.* (1999), Chinn (2002) and Zipperian (2011) are 200 N over six specimen mounts which are normally 32 mm in diameter. Zipperian (2011) points out that in fact for hard specimens, such as ceramics, in softer mounts, the real pressure applied is over the specimen area rather than the mount area. Thus, 40 kPa grinding/polishing pressures resulting from the application of 200 N to six 32 mm mounts is amplified to 410 kPa if the mounted ceramic specimens are 10 mm in diameter. Clearly, the polishing pressure on the specimen is much reduced if the mount is filled with a ceramic filler i.e., it will be very close to 40 kPa. While increased polishing pressures yield greater material removal rates, Elssner *et al.* (1999) points out that reductions in polishing pressure reduce the likelihood of pull-outs occurring, which is very important if porosity is being assessed and examined.

Abrasive Systems for Grinding

Grinding systems can be based on fixed, semi-fixed or freely rolling abrasives (Elssner *et al.*, 1999; Chinn, 2002; Täffner *et al.*, 2004; Vander Voort, 2009; Zipperian, 2011). Typical fixed abrasives are traditional SiC papers used in metallography and diamond fixed by resin or metal bonding into a platen. These platens comprise raised islands with depressed reservoirs between them to retain coolant/lubricant and to allow swarf to be taken away from the surface being ground. Fig. 10(a) shows an example of a fixed diamond grinding platen. From current consumables catalogs, typical diamond grit sizes available range from 240 to $3\ \mu\text{m}$. Semi-fixed abrasive systems comprise abrasive grits retained in lower recesses of a platen (e.g., concentric or spiral grooves or in regions between raised circular or hexagonal structures) fabricated from a composite or resin Fig. 10(b) shows an example of such a platen. Raised areas act as lapping surfaces where abrasive grains cut the specimen surface by a rolling action, thus removing material. Material removal is also effected by machining by abrasive particles which can be temporarily fixed by being entrapped at the interface between the raised part of the platen and the groove/recessed area (see Zipperian, 2011). For the semi-fixed abrasive system, diamond slurries or suspensions are applied to the platen surface. Such slurries/suspensions can also be used in conjunction with a metal mesh platen where recessed areas away from the metal hold the coolant and abrasive and the top part of the metal mesh is able to hold temporarily fixed abrasive particles in contact with the glass, glass ceramic or ceramic being ground. The most gentle mode of specimen grinding is lapping (Elssner *et al.*, 1999). In lapping, freely moving abrasive particles, typically SiC or diamond grits, roll between the specimen being ground and a cast iron wheel.

The choice of coolant/lubricant for specimen grinding depends on the nature of the specimen. If any parts of the specimen (e.g., surface layers, surface contaminants, internal phases) are water soluble or readily undergo hydrolysis, non-aqueous fluids must be used. A typical non-aqueous fluid would be alcohol based. If neither water solubility or hydrolysis are potential problems, water or water based lubricants can be used. In general, water is a recommended lubricant for fixed abrasive platens, whilst diamond suspensions used for grinding are suspended in lubricants. Again, perusal of consumables available from Struers, Buehler or PACE Technology and others shows both aqueous or non-aqueous lubricants/coolants to be available, as well as diamond suspensions which have aqueous or non-aqueous carrier fluids.

An Overview of Grinding and Polishing

Introduction

It is virtually impossible to recommend specific polishing methodologies for glasses, glass ceramics, ceramics and ceramic matrix composites, since they are often specific to an individual or a metallographic supplies vendor. Mörtel (1991), Elssner *et al.* (1999), Chinn, (2002), Xie *et al.* (2003), Täffner *et al.* (2004), Geels *et al.* (2007), Vander Voort (2009), Zipperian (2011) and Buehler (2020) all give excellent “Recipes” for arriving at a perfectly polished specimen for subsequent ceramographic examination before or after etching. The following sections attempt to provide background to planar grinding, fine grinding and polishing such that generalities in the “Recipes” are drawn out. One parameter that is not commented on is the time taken for the various stages. This is because they vary widely. For example, Xie *et al.* (2003) use a total grinding and polishing time of 1 h 40 min for the fine grinding and polishing of α -sialons whilst Zipperian (2011) recommends 15 min total fine grinding and polishing time for the engineering ceramics ZrO_2 , SiAlON and Si_3N_4 . How long each grinding and polishing stage will be determined by the person doing the ceramographic preparation.

The following sections apply to machine grinding and polishing with specimens clamped in a holder which has a central load applied. During the preparation of specimens, it is absolutely essential that the specimens and holder are thoroughly cleaned between each grinding and polishing stage. It is useful too if platens are cleaned with a mild detergent solution and rinsed after each use. This is because swarf and congealed coolant/diamond suspension can accumulate during use. Any washing up brushes should be specifically kept for a specific abrasive size to avoid the potential for cross-contamination. In addition, it is essential that specimens are not removed from the holder during cleaning because it is impossible to return the specimen to the exact position and height with micron precision. Thus, it is good to have the use of an inverted microscope to be able to look at specimen surfaces during grinding and polishing.

Planar grinding

Following sectioning and mounting, a specimen is ground before polishing. The grinding process comprises two stages: planar grinding and fine grinding. Planar grinding involves the flattening of the specimen and mount surface such that they are completely level and the specimen has a uniform level of surface roughness and material damage across its area. The grade of abrasive and the process by which planar grinding is carried out depends upon the material. Thus, for glasses, glass ceramics and softer/porous ceramics which may have been sawn using a fine diamond grit, a reasonably fine abrasive can be used which is either fixed or semi-fixed. Abrasives which can be employed are silicon carbide, cubic boron nitride or diamond. Quite frequently, silicon carbide papers used for metallographic preparation can be used. For harder and tougher ceramics and ceramic matrix composites, a coarser abrasive should be employed, because the diamond grit size used for sectioning is also coarser. For these materials, diamond is the strongly preferred abrasive. For electronic ceramic specimens containing metallic interlayers, fixed abrasives are preferred since they much reduce the potential for abrasive particles to become embedded in the metallic layers leading to loss of microstructural detail.

From the various methodologies for polishing ceramics and glasses given by (Elssner *et al.*, 1999; Chinn, 2002; Täffner *et al.*, 2004; Geels *et al.*, 2007; Vander Voort, 2009; Zipperian, 2011) the following can be said. In general, planar grinding employs abrasive sizes in the range 30–60 μm with fixed abrasives and water cooling unless the specimen type precludes this. Forces employed are generally in the range 35–40 N per sample and grinding platen rotation speeds are 200–300 rpm. Both contra and complementary rotations are suggested!

Fine grinding

Fine grinding is carried out after planar grinding, once the specimen is plane and coplanar with the mount. Glasses, glass ceramics and less dense materials can continue to be ground using silicon carbide papers. However, as Geels *et al.* (2007) point out silicon carbide abrasive particles are rapidly worn down by comminution and so lose their cutting ability in a minute or two. Incidentally, this is not the case for polycrystalline diamond, where comminution rates are much less. It is normal to go down through the grades of silicon carbide abrasive papers. Abrasive sizes are characterized using US mesh sizes or European grain sizes (see Elssner *et al.*, 1999; Zipperian, 2011). The references give the corresponding grit sizes in μm . Again, consulting the various methodologies given by Elssner *et al.* (1999), Chinn (2002), Täffner *et al.* (2004), Geels *et al.* (2007), Vander Voort (2009) and Zipperian (2011), typical abrasive sizes used are 15, 9 and 6 μm or their US or European grit/grain size equivalents. Platens can be silicon carbide papers for softer materials and this type of grinding is preferred for electronic and porous ceramics. For hard tough materials, fixed diamond abrasives are often used, particularly for the first fine grinding stage. For finer grinding, semi-fixed abrasive platens with diamond suspensions are used. These can be resin based or metal mesh or indeed hard napless polishing papers able to hold abrasive and coolant in perforations or spaces in between woven hard fibers (see Geels *et al.*, 2007 Table 13.1 for typical types of platens). Platen rotation rates suggested are in the range 150–200 rpm with both complementary or contra rotation of the specimen holder. Forces between 35 and 40 N are suggested except for glasses where loads of about half these values are suggested (see Buehler, 2018b).

Polishing

Polishing of glasses, glass ceramics and ceramics is carried out on cloths which have been specifically developed for the purpose. Chinn (2002) and Geels *et al.* (2007) list the types of cloth types available, and, although some trade names of available cloths may have changed, the descriptions of their characteristics are still valid (see for example the cloth descriptions in Buehler, 2018b). Generally, hard woven cloths are preferred as they lead to good specimen flatness and edge retention. These cloths have little pile or nap and so instead of diamond particles being presented to the specimen surface on individual strands of the cloth, fine

diamond particles are held in perforations or spaces in between hard woven fibers as for fine grinding (Section “Fine Grinding”). In certain instances, it may be beneficial to use a napped cloth because its mode of abrasion causes areas of different hardness in the specimen to be revealed as material removal rates from softer phases or grain orientations will differ. This type of polishing is referred to as relief polishing, because it generates areas of slightly different heights allowing phase or grain structures to be visible without etching or scanning electron microscopy contrast.

Polishing uses diamond grit sizes of 6, 3, 1 and 0.25 μm which are suspended in aqueous or non-aqueous suspensions and used with coolants/lubricants of the same type. The amount and viscosity of the coolant/lubricant employed can affect material removal rates. This is because too little allows the abrasive particles to penetrate most deeply into the specimen, while too much leads to a lubricant film with a thickness close to the abrasive size leading to virtually no material removal (see [Elssner et al., 1999](#)). Some authors suggest that lower platen rotation speeds are reduced for polishing while others suggest they are held at the same level as for fine grinding. Given that material removal with minimum subsurface damage is required, then it is probably preferable to keep the speed high and reduce to the applied loads.

Increased rates of material removal can be achieved by a chemo-mechanical polishing (CMP) approach. CMP involves the use of abrasive nanoparticles of for example: silica, alumina, ceria iron oxide and chromium oxide. [Zipperian et al. \(1992\)](#) shows decisive proof that CMP of silicon nitride gives greatly enhanced surface finish and a smoother finish, with R_a values being about 1/3rd of those for a mechanically polished specimen. Which abrasive to use and at what pH are of course material dependent and detailed advice can be sought from consumables suppliers (e.g., Struers, Buehler, PACE Technologies). [Wisniewski et al. \(2011\)](#) used CMP to enable them to obtain the low levels of surface damage needed for the acquisition of Electron Back Scattered Diffraction (EBSD) data of sufficient quality to facilitate crystallographic analysis of the surface crystallization of fresnoite glass ceramics. An alternative way of achieving a surface with minimal surface damage is vibratory polishing ([Buehler, 2018a](#)). In vibratory polishing, a specimen is held within a weighted holder which is free to move on the surface of a polishing cloth located on a vibrating base. The specimens oscillate up and down and move around a containment bowl ([Geels et al., 2007](#)) and this results in sufficient relative motion for gentle material removal. If necessary, CMP polishing suspensions could be used for vibratory polishing.

It is important to note that more gentle material removal rates yield more faithful 2D representations of 3D microstructures. This is particularly so for porous materials as well as materials where grain pull outs often accompany ceramographic preparation. Thus, for ceramic materials containing porosity, it is worthwhile assessing porosity levels as polishing is carried out. If the true microstructure has been revealed, the porosity levels will be seen to be similar after different times of polishing.

Etching

Introduction

In ceramography, etching is a broad term, encompassing chemical and physical methods, as well as a combination of both, used to reveal visible contrasts in microstructure. In this context, visible refers to the resolution of microstructural detail in optical or scanning electron microscopes. In general, the features revealed by etching are grain boundaries. However, surface faceting of grains can also be observed. In general, because of their chemical stability, ceramics require highly aggressive attack by chemical etchants with attendant levels of danger which should be acknowledged by the use of appropriate personal protective clothing and behavior while etching. The severity of the etching process may require specimens to be removed from their mounts. This is particularly the case for etching specimens in molten salts or etching them at high temperature (thermal etching).

[Mörtel \(1991\)](#), [Elssner et al. \(1999\)](#), [Chinn \(2002\)](#) and [Täffner et al. \(2004\)](#) all give tables of chemical etchants for a wide range of oxide and non-oxide ceramics. In addition, they give alternative or additional etching methods such as electrochemical, thermochemical, thermal, relief polishing, ion polishing, plasma etching and “etching” by tinting using heat or thin films. Clearly, the lists of etchant recipes and methodologies provided by [Mörtel \(1991\)](#), [Elssner et al. \(1999\)](#), [Chinn \(2002\)](#) and [Täffner et al. \(2004\)](#) do not need repeating. However, this section will briefly describe each etching process and where possible show a representative micrograph.

It cannot be stressed enough that etching can involve the use of dangerous chemicals and gases as well as high temperatures and that every possible measure is taken to follow safety guidelines from MSDS sheets as well as laboratory safety rules.

Before Etching

Three levels of examination should be completed before etching. These are: hardness or microhardness tests ([Chinn, 2002](#)), porosity measurements ([Chinn, 2002](#)) and chemical analysis by energy or wavelength dispersive X-ray analysis. Clearly, etching attacks the surface structure of the ceramic or glass and so accurate hardness or microhardness values will be compromised by a softer “top layer”, the depth of which will determine the deviations from true values. In some instances, particularly chemical etching, porosity levels can be increased due to preferential removal of micron size second phases which are more susceptible to solution in the etchant which leads to erroneous porosity data. The quality of chemical analysis using a scanning electron microscope fitted with X-ray analysis spectrometers can be adversely affected by etching. This is because certain phases can be removed by etching (e.g., glass in alumina by phosphoric acid etching). Thus, the overall composition of the surface layers of the alumina would be richer in aluminum than the bulk of the ceramic which contained an aluminosilicate glass phase.

Removal of Specimens From Mounts

If the etchants to be used are likely to attack the mounting material (see Zipperian, 2011) or the mount is likely to be heated to above its maximum use temperature, it may be necessary to remove the specimen from the mount before etching (Geels *et al.*, 2007). Chinn (2002) suggests sawing the mount material away from the specimen, leaving a 1 mm margin using a diamond sectioning saw. The remainder of the resin can then be removed by heating to cause the resin to combust or pyrolyse. This process should render the remnant mounting material powdery and easily removable. It is to be noted that the heating process should be conducted under a fume hood. Alternative methods of removing the residual resin after sawing are: (1) immersion of the specimen in M-Pyrol (N-Methyl-2-Pyrrolidone) or (2) immersion in N,N-Dimethyl-formamide at 150°C (Geels *et al.*, 2007). It is of course essential to follow safety guidelines when using these chemicals. Following complete removal of the specimen from the mounting material, it is always recommended that identifying saw cuts are made into back of the specimen away from the polished face. There is nothing more annoying than trying to keep unmarked specimens in a specific order on a tile or crucible only to mix them up by dropping them or some other accident!.

Etching Methods

Relief etching (polishing)

The methodology of relief polishing, which is also relief etching, is described in Section “Polishing” above. An example of a microstructure prepared using relief etching (polishing) is given in Fig. 11. As pointed out by Chinn (2002) the technique is straight forward. However, problems can arise such as edge rounding and because the very process involves generating phases or grains with different respective heights, higher magnifications in optical microscopy may be limited because of their small depth of field. It appears generally accepted that relief etching is a preferred method of “etching” metallized ceramics or electronic ceramics containing metallic electrodes.

Thermal etching

Heating a polished ceramic surface to a high enough temperature results in the formation of grooved grain boundaries and curved grain surfaces (Geels *et al.*, 2007). Calderon-Moreno and Schehl (2004) show representative micrographs of an alumina-zirconia specimen which has been thermally etched (see Fig. 12). The specimen shown in Fig. 12 was sintered at 1600°C and then thermally etched in air at 1400°C for one hour. The grooving of the grain boundaries and some curving of grain surfaces can be clearly seen in Fig. 12. The thermal etching temperature is consistent with the suggestions made by Elssner *et al.* (1999) and Chinn (2002) of temperatures 100–200°C below the sintering temperature. Typical times range from a few minutes to two or more hours. Thermal etching is an oft used etching method and Elssner *et al.* (1999), Chinn (2002) and Täffner *et al.* (2004) indicate its use for alumina, barium titanate, cemented carbides, cordierite, lanthanum strontium manganese oxide, silicon carbide, silicon nitride, spinel, titania and zirconia. For the non-oxide ceramics, care needs to be taken with respect to the gaseous environment. Nitrogen or a vacuum can be used for silicon nitride. For carbide ceramics it is necessary to use an inert gas (e.g., argon) or a vacuum.

Based on experience, it must also be said that the furnace environment must be clean and it is preferable if the specimen is housed within a pure alumina tube or chamber. This is because contaminants can be released from typical muffle or tube furnaces which can condense on to the specimen during thermal etching, leading to fields of view which are annoyingly compromised in terms of quality and clarity. Other limitations of thermal etching are (1) The potential for grain growth at the high temperatures involved and (2) the possibility of significant specimen damage if the material is allotropic. Chinn (2002) warns of potential problems etching zirconia due to phase transformations e.g., monoclinic to tetragonal which can generate transformation stresses sufficient to destroy a carefully prepared ceramographic specimen!.

Chemical etching

Chemical etching involves the removal of areas of lower chemical stability from the specimen surface. These areas may be a second phase, e.g., an intergranular glass, or grain boundaries whose energies are higher than the grains they surround and so are attacked preferentially. As previously mentioned, there are many chemical etchants. Many are based upon hydrofluoric acid used alone or mixed with other chemicals e.g., hydrochloric acid, nitric acid, methanol (see Chinn, 2002). Such etchants are used at room temperature. Other strong acids are used, boiling, e.g., H_3PO_4 for alumina and mullite. Molten salts are also used as chemical etchants. Cook *et al.* (1995) used molten 90 wt% KOH:10 wt% KNO_3 to etch sintered silicon carbide, siliconized silicon carbide, pressureless sintered silicon nitride and a $z = 0.5$ β -sialon. The temperature used was 480°C and the time 15 min. These authors indicated that the molten salt etch was the best method out of six tried for all but the siliconized silicon carbide. In the writer's experience, molten salt etching can be a very useful etching method for non-oxide ceramics. However, much care taken needs to be taken to get etching times correct so as not to etch the matrix grains or require much post etching cleaning. Quite often a glass like contaminant remains on the surface of the etched ceramic which compromises examination of the true microstructure and reimmersion in the molten salt is the only way to remove it. An example of a microstructure produced using chemical etching is shown in Fig. 13.

Electrolytic etching

Electrolytic etching is applicable to ceramics showing some conductivity e.g., carbides and ZrB_2 (Elssner *et al.*, 1999; Chinn, 2002). Typically, the specimen is held either in a conductive mount or a hole is drilled in the back or side of the mount to allow electrical contact to be made with the aid of a screw. Using a suitable DC power supply, the specimen is made anodic with respect to a cathodic cup in which the electrolyte is held. Examples are the etching of titanium carbide using 1% KOH solution at 5 volts for 4 min (Chinn, 2002) and the etching of B_4C in 0.1% KOH with a current density of 0.1 A cm^{-2} for 30–60 s (Rehman *et al.*, 2015). The microstructure arising from the latter etching process is shown in Fig. 14.

Fig. 13 Microstructure of silicon carbide densified with Y_2O_3 , Al_2O_3 and SiO_2 after etching with boiling Murakami's solution (15 g KOH + 15 g $\text{K}_3\text{Fe}(\text{CN})_6$ + 60 ml H_2O) for 5 min. Microstructure and mechanical properties of B₄C densified by spark plasma sintering with Si as a sintering aid. *Ceramics International* 41, 1903–1906.

Plasma etching

The characterization of sintered silicon nitride, sialon and silicon carbide microstructures has been made significantly easier by the use of plasma etching. The micrograph shown in [Fig. 1\(b\)](#) was generated by plasma etching using a CF₄ oxygen gas mixture. The ionized CF₄ gas preferentially removes silicon atoms from the surface and thus the silicon nitride grains are preferentially removed as SiF₄. This leaves the glass phase standing slightly proud of the surface enabling excellent contrast for imaging. There are many other examples in the literature because of the clarity of image which can be obtained by scanning electron microscopy. Plasma etching systems are readily available due to their use in the electronics industry and small laboratory systems are available not only for etching but also for cleaning samples before SEM or TEM examination.

Less common etching methods

Thermochemical etching involves the use of a two stage etching process. In the first instance specimens are etched chemically and then they are subsequently thermally etched. The temperature at which the ceramic is thermally etched is much reduced compared to that used for thermal etching alone. [Chinn \(2002\)](#) indicates that alumina sintered at 1630°C could be thermochemically etched at 1150°C after chemical etching for two or three minutes. [Chinn \(2002\)](#) also recounts the etching of nickel-zinc-ferrite (Ni_{0.5}Zn_{0.5}Fe₂O₄) sintered at 1240°C could be thermochemically etched at 850°C after chemical etching. In both cases the chemical etchants were mixtures of orthophosphoric acid and nitric acid. Advantages claimed are that the lower thermal treatment temperatures reduce the likelihood of grain growth and surface modification. It should be noted that for thermal etching alone, alumina would require a temperature of 1500°C rather than the 1150°C used for the thermochemical etching.

Ion etching involves the exposure of a polished specimen surface to a beam of argon or krypton ions incident at angles of between 5° and 60° ([Mörtel, 1991](#)). The ion bombardment causes grain boundaries and grains with different orientations to undergo different rates of ion milling, resulting in relief effects being generated by the glow discharge based process. [Mörtel \(1991\)](#) reports the use of ion etching for silicon nitride and zirconia, while [Chinn \(2002\)](#) recommends the technique for alumina, sialon, silicon carbide and urania. The technique is may also be used for AlN and lead zirconium titanate (see for example see “Relevant Website section”).

Tint etching and interference film etching are specialist techniques for optical microscopy. The interested reader is directed toward excellent descriptions of the techniques by [Elssner et al. \(1999\)](#) and [Chinn \(2002\)](#). They are frequently used in conjunction with differential interference contrast optical microscopy (see [Geels et al., 2007](#)) for an explanation of this microscopic technique.

Concluding Remarks

In conclusion, it can be said that there is plenty of useful background information relating to sectioning, mounting, planar grinding, fine grinding, polishing and etching. However, as the reader will have noticed very few of the sources of information for this chapter are less than a decade old. This is not a great problem as many of the developments of equipment, accessories and consumables appear to be for reliability and patent reasons rather than radical technical change. The suppliers websites are a great source of background information. However, because a significant majority of their business is metallurgy related, much of this information is not ceramic related. That said, the suppliers and their agents will willingly help with developing a specific sectioning, mounting, planar grinding, fine grinding and polishing régime for a particular ceramic and so a researcher should not hesitate to contact them. Useful troubleshooting analyses are given in the publications of [Geels et al. \(2007\)](#) and [Zipperian \(2011\)](#). Help with etching is a little more difficult to attain except from research colleagues.

As mentioned in the very first sentence of Section “Introduction”, the phrase “samples were mounted, ground and polished” is of little use to the inexperienced researcher and so it would be highly beneficial to all in the field of ceramics and glasses research, if specimen preparation techniques were reported in the literature. In many ways this is as important to the “budding researcher” as a description of how the material was prepared!!!!.

Scanning Electron Microscopy for Ceramics and Glasses

Michael J Pomeroy, University of Limerick, Limerick, Ireland

© 2021 Elsevier Inc. All rights reserved.

Introduction

Scanning Electron Microscopy (SEM) was first conceptualized in 1935. However, it was not until 1965 that the first commercially available instruments were available. Since 1965 many, many improvements in the design of vacuum systems, electron columns and lenses as well as great improvements in computer controls have been effected. These improvements have all contributed to increases in resolution, such that instrument manufacturers are able to quote better than 1 nm resolution, depending on microscope operating parameters. A facility to use SEMs in low vacuum mode has greatly improved their versatility. This is especially the case for biological specimens which may relate to or be attached to biomedical ceramics and glasses. In addition, in-situ experiments can be conducted. Such experiments can be listed as: tensile testing, heating/cooling stages with very high heating/cooling rates, electrical testing, cathodoluminescence.

The first electron probe microanalysis systems, based upon wavelength analysis became readily available toward the late 1970s. Since that time, major changes have also occurred with the advent of energy dispersive X-ray analysis and more recently, soft X-ray emission analysis. In addition to X-ray analysis, it is possible to obtain chemical information from the top few nanometers of surface using Auger electron spectroscopy.

By analyzing the diffraction of electrons backscattered from the surface layers (over a depth of about 10–40 nm) with a plate analyzer, the crystallography of a specimen can be ascertained in terms of spatial distribution, crystallographic orientation and texture. Using this analytical method, grain shapes and sizes and the nature of grain boundaries can also be quantitatively assessed.

The introduction of dual SEM/FIB (Focused Ion Beam) systems has revolutionized the ability to examine a specimen using SEM, decide on a micro-feature of specific interest and then excise a cross-section of that micro-feature in its surroundings for more detailed transmission electron microscopy. Add to this capability the incorporation of an electron detector below the specimen and in-SEM STEM (scanning transmission electron microscopy) is possible! Add to this an annular dark field contrast facility and STEM with chemical contrast can be readily carried out.

In short, current SEM instruments cover a wide range of imaging capability for the analysis of a wide range of ceramics, glass-ceramics and glasses. The backgrounds to the various techniques will be outlined and examples of images and analytical data given.

Anatomy of a Scanning Electron Microscope

The schematic diagram in the work by Szyrkowska (2005), shown in Fig. 1, gives a suitable indication of the anatomy of a scanning electron microscope. As indicated by Fetzer *et al.* (2021), electrons are produced by thermionic or field emission filaments in electron microscopes. In the case of SEMs though, accelerating voltages are up to 40 kV rather than 200–300 kV as for TEMs. Again, as described by Fetzer *et al.* (2021), the beam is demagnified and focused using electromagnetic lenses and apertures and then rastered across a sample surface by the action of scan coils. The objective lens is the final lens before the sample and the sample may or may not come under the influence of the magnetic field of the lens. Goldstein *et al.* (2003) define the type of objective lens with respect to the relative position of the specimen. Thus, if the sample is outside the lens' magnetic field influence, it is referred to as a pinhole lens, if the sample is wholly within the magnetic field of the lens it is referred to as an immersion lens and if it is not within the magnetic field but under its influence, the lens is referred to as a snorkel lens. The quality of the electron beam is dependent on the electron source size and the energy spread of the electrons defined as $(\Delta E/E_0)$, where ΔE is the spread, and E_0 the accelerating voltage. The former controls spherical aberration and the energy spread chromatic aberration. The full width at half maximum beam intensity, d_p , of the electron beam is heavily dependent on its brightness (β) which is defined in Eq. (1).

$$d_p = \sqrt{\frac{4 \cdot i_p}{\beta \cdot \pi^2 \cdot \alpha^2}} \quad (1)$$

where, i_p and α are probe/beam current and convergence angle.

Table 1 gives data for brightness, source size, energy spread, expected filament life and the beam stability. Clearly, the FEG filaments have the best brightnesses and lowest energy spreads. In particular, the cold FEG filament produces a beam with the best combination of brightness, source size and energy spread. As source size controls spherical aberration and energy spread controls chromatic aberration (see Fetzer *et al.* (2021)) for an explanation of these aberrations, then the small source size and low energy spread will be minimized for the cold FEG system, giving a very bright beam with the minimum aberration problems and hence very high image resolution. The hot FEG and Schottky emitters also appear to have good characteristics. In fact the Schottky emitter is preferred for SEMs fitted with analytical X-ray systems due to the excellent beam stability ($\sim 1\% \text{ h}^{-1}$). This beam stability is important for quantitative X-ray analysis where consistency of beam is important.

Fig. 1 Schematic of a scanning electron microscope. Reproduced from Szykowska, M.I., 2005. Microscopy techniques: Scanning electron microscopy. In: Worsfold, P., Townshend, A., Poole, C. (Eds.), *Encyclopedia of Analytical Science*. Netherlands: Elsevier, pp. 134–143.

Table 1 Typical properties of electron beams emitted by different sources

	Brightness ($\text{A cm}^{-2} \text{ sr}^{-1}$)	Source size	Energy spread ΔE (eV)	Life (h)	Stability (% per h)
W hairpin	10^5	30–100 μm	1 to 3	≤ 100	1
LaB ₆	10^6	5–50 μm	1 to 2	≤ 1000	1
Cold FEG	10^8	$< 5 \text{ nm}$	0.3	≥ 1000	5
Thermal FEG	10^8	$< 5 \text{ nm}$	1	≥ 1000	5
Schottky	10^8	$< 15\text{--}30 \text{ nm}$	0.3 to 1	≥ 1000	~ 1

Note: Data taken from Goldstein, J., Newbury, D.E., Joy, D.C., et al., 2003. *Scanning Electron Microscopy and X-Ray Microanalysis*, third ed. US: Springer.

Although the thermionic emission filaments appear to offer much lower quality electron beam generation, they are wholly adequate for a very large fraction of scanning electron microscopy requirements. In particular, their use in SEMs for X-ray analysis is wholly adequate due to the interaction volume between electron beams and specimens where X-rays are generated being independent of d_p , i_p and α , which is explained later.

As shown in Eq. (1), probe size is clearly related to probe current, i_p . Deeper analysis shows that other parameters related to aberration and wavelength (dependent on accelerating voltage), as well as i_p , control the minimum probe size. Goldstein et al. (2003)

show how probe size and probe current are related for cold FEG, Schottky and tungsten filaments for 1, 10 and 30 kV accelerating voltages. The graphical relationships show, as expected, that the smallest probe size arises for the cold FEG filament. However, depending on accelerating voltage, for high probe currents, exceeding about 200 pA, Schottky emitters develop smaller probe sizes. Tungsten thermionic filaments have probe sizes which are between 10 and 20 times that of a FEG source for 30 and 10 kV accelerating voltages.

In the analysis of electron probe size, it is of course assumed that the cross-section of the beam is circular. Under certain circumstances however, the beam cross – section may be elliptical. This is manifested by images which appear to flow in x, y or x-y directions depending on the location of the major and minor ellipse axes. This image flow is clearly visible when as the focus is manipulated between under- and over-focus as shown in JEOL (2020a). In order to obviate this imaging artifact, referred to as astigmatism, an octupole stigmator with four sets of magnetic poles is used to manipulate the beam shape from elliptical to circular and thus greatly improve image quality (Goldstein *et al.*, 2003).

Interactions of an Electron Beam with Materials

When electrons in an incident beam enter a material, they are scattered both elastically and inelastically. Elastically scattered electrons undergo changes in direction without changing their energy, whilst inelastically scattered electrons change not only direction but also their energy. These energy losses induce the generation of secondary electrons as well as X-rays. The depth to which incident electrons can penetrate a solid is dependent on their rate of energy loss per unit distance traveled in the material (dE/ds). This rate of energy loss is affected by material density (ρ), atomic number (Z), atomic weight (A), the electron energy at any point in the material (E_i) and the average energy loss per scattering event. Eq. (2) gives the expression for dE/ds .

$$\frac{dE}{ds} = -7.85 \times 10^4 \cdot \frac{Z \cdot \rho}{A \cdot E_i} \cdot \ln \left(\frac{1.166 \cdot E_i}{J} \right) \quad (2)$$

where

$$J = (9.76 \cdot Z + 58.5 \cdot Z^{-0.19}) \times 10^{-3} \quad (3)$$

Various Monte Carlo simulations of electron trajectories in materials have been presented and Fig. 2 shows those typical of C, Si, Ag and Au. It is of interest that the simulations describe a semi-circle meaning that beneath the impact point of an incident electron beam, electron scatterings result in electron trajectories fanning out, but being bounded by a hemispherical boundary. For an accelerating voltage of E_0 , Kanaya and Okayama (1972) consider that 90% of all beam interactions occur within a hemispherical volume with a radius (R_0) given according to Eq. (4). Table 2 shows typical R_0 values calculated for accelerating voltages of 20, 15 and 10 keV for selected relevant materials. Should the beam impinge at an angle i.e., when the sample is tilted at an angle θ to the incident beam this radius (R_θ) decreases according to Eq. (5). However, due to the fact that forward scattering within shallow depths occurs, the backscattered electron yield is enhanced despite the overall interaction volume being less.

$$R_0 = \left(\frac{0.0276 \cdot A}{Z^{0.89} \cdot \rho} \right) \cdot E_0^{1.67} \quad (4)$$

$$R_\theta = R_0 \cdot \cos(\theta) \quad (5)$$

Only certain of the scattered electrons reemerge from the surface, such that they can be captured by a detector. These electrons, referred to as backscattered electrons, come from depths which are between 30% and 60% of the value of R_0 for zero tilt angles. Eq. (6) gives the fractional depth, y_D , from which 95% of backscattered electrons emanate from the surface as a fraction of R_0 , for an accelerating voltage of 20 keV. This fractional depth is important, since it allows prediction of the depth from which 95% of the information, viewed as an image, comes. For lower accelerating voltages (10 keV and below), far more of the signal reaching the electron detector is from shallow depths. Thus, the values of y_D are further diminished in this instance. The lateral distance electrons can

Fig. 2 Monte Carlo simulations of electron scattering within different elements: C, Si, Ag and Au. Reproduced from Szyrkowska, M.I., 2005. Microscopy techniques: Scanning electron microscopy. Table 2 R_0 values calculated using Eq. (4) for different accelerating voltages for C, Al_2O_3 , Si_3N_4 , a YSiAlON glass and ZrO_2 .

	R_0 values (μm) for 0° tilt angle		
	20 keV	15 keV	10 keV
C	4.4	2.7	1.4
Al_2O_3	2.8	1.8	0.9
Si_3N_4	3.1	1.9	1.0
YSiAlON(gl.)	3.1	1.9	1.0
ZrO_2	1.6	1.0	0.5

Table 3 R_0 , R_{BS} , D_{BS} and η values calculated for an accelerating voltage of 20 keV using Eqs. (4) and (6)–(8) for C, Al_2O_3 , Si_3N_4 , a YSiAlON glass and ZrO_2

	R_0 (μm)	R_{BS} (μm)	D_{BS} (μm)	η
C	4.4	2.7	1.4	0.06
Al_2O_3	2.8	1.7	0.8	0.12
Si_3N_4	3.1	1.8	0.9	0.12
YSiAlON(gl.)	3.1	1.7	0.9	0.16
ZrO_2	1.6	0.8	0.4	0.21

travel within a sample and be ejected as backscattered electrons can be calculated as a function of Z also. Eq. (7) gives an expression for y_R , the fractional lateral distance with respect to R_0 , from which 95% of backscattered electrons emanate. Again, it is seen that y_R is dependent solely on Z .

$$\gamma_D = 0.333 - 0.00374.Z + 2.469 \times 10^{-5}.Z^2 \quad (6)$$

$$\gamma_R = 0.675 - 0.00975.Z + 6.3 \times 10^{-5}.Z^2 \quad (7)$$

$$\eta = -0.0254 + 0.016.Z - 1.86 \times 10^{-4}.Z^2 + 8.3 \times 10^{-7}.Z^3 \quad (8)$$

$$Z_{av} = \sum_0^i x_i.Z_i \quad (9)$$

From the analysis so far, it is clear that for a fixed accelerating voltage, the radius of the interaction hemisphere and also the fractional depth associated with signal generation is heavily dependent on Z , the atomic number. One might expect therefore that the intensity of backscattered electrons might also be dependent on Z . This is indeed the case and Eq. (8) shows how the backscatter coefficient, η , is related to Z . η is also defined as the ratio of the number of backscattered electrons (n_{BSE}) to incident electrons in the incident electron beam (n_B). This can of course related to the ratio of backscattered electron beam current to incident beam current (i_{BSE}/i_B). For ceramics and glasses, it is important to be able to calculate the average atomic number for the composition (Z_{av}). This is done using Eq. (9) where x_i is the atom fraction of constituent i , and Z its atomic number. Using Eqs. (4) and (6)–(8), values of R_0 , radii from which backscattered electrons emanate, R_{BS} , backscattering depths, D_{BS} , and η can be calculated. This calculated data is presented in Table 3 for C, Al_2O_3 , Si_3N_4 , a YSiAlON glass and ZrO_2 .

Fig. 3 illustrates the variation of backscattered electron coefficient, η , with Z for $Z = 6$ to $Z = 80$. It is seen that low atomic number elements have very low coefficients compared to the higher atomic number elements. Fig. 4 shows a backscattered electron image of a crystallized yttrium-SiAlON glass from original work by the writer and co-workers. The micrograph shows three distinct contrasts black, light gray and white. X-ray diffraction showed the phases silicon oxynitride ($\text{Si}_2\text{N}_2\text{O}$) residual yttrium-SiAlON glass with a modified composition and yttrium disilicate ($\text{Y}_2\text{Si}_2\text{O}_7$) to be present in the material. Given the average atomic weight for silicon oxynitride is 10, that for yttrium disilicate is 14.7 and original glass 13.2, the observed contrasts are clearly in accordance with the phases present. Incidentally, the contrast, C , between two phases is given by the ratio $(\eta_2 - \eta_1)/\eta_2$, where $\eta_2 > \eta_1$. Thus, for high average atomic number phases, contrast between them is less than for low average atomic number phases e.g., $\text{Si}_2\text{N}_2\text{O}$ and yttrium SiAlON glass.

Secondary electrons in loosely bound outer shells are released as a result of inelastic scattering effects associated with backscattering electrons. Secondary electrons are emitted over a depth of 5 mean free paths of an electron in a material. Typically, the mean free path of an electron in ceramic materials is in the region of 2.5 nm and so the depth from which a signal could be captured from a secondary electron is about 12.5 nm. Secondary electrons can be formed when the electron beam enters the specimen as well as when backscattered electrons leave the specimen. Fig. 3 shows the variation in the secondary electron yield coefficient with atomic number. For secondary electrons, the variation in yield coefficient with atomic number is negligible once an atomic number of about 15 is exceeded. As imaging is in effect a resolution of different contrasts and the electron yield controls that contrast, then only backscattered electron images can afford chemical contrast imaging over the whole range of atomic

Fig. 3 Effect of atomic number on secondary electron yield coefficient (δ) and backscattered electron yield coefficient (η).

Fig. 4 Backscattered electron image of crystallized yttrium-SiAlON glass. White phase yttrium disilicate (av. At. No. = 14.7), black phase silicon oxynitride (av. At. No. = 10), gray phase residual yttrium-SiAlON glass. (White bar = 10 μm).

number. Secondary electron contrast is limited in the main to topographical contrast. **Fig. 5** shows a typical secondary electron image. The topographical detail is clearly evident in this image. The topographical contrast arises from the manner in which secondary electrons are generated since where the incident beam enters perpendicularly to the surface less secondary electrons are produced than when it enters obliquely (see [JEOL, 2020b](#)). However, the particular image in **Fig. 5** is probably generated from mixed secondary and backscattered electrons emanating from the surface.

Secondary electrons have a very low energies (50 eV or less ([JEOL, 2020b](#))) compared to backscattered electrons whose energy extends from that energy up to that associated with the accelerating voltage. Typical electron detectors in SEMs are of the Everhart-Thornley (E-T) type (see **Fig. 6**) where a biased Faraday cage guides electrons onto a scintillator disc. The light pulses thus generated are guided by a light pipe to a photomultiplier tube. When the detector is negatively biased, secondary electrons are rejected from detection, meaning that the resulting images are backscattered electron images. If positively biased, the image is constructed from secondary electrons, augmented by a few backscattered electrons. Thus, by varying the bias on the E-T detector, relatively true secondary electron images can be obtained. One useful application of changing this bias is to reduce charging effects which are manifested by a series of horizontal line distortions of SEM images. The low energies of the secondary electrons means that their paths can be readily disturbed by electrostatic effects such as charging. This is not the case for backscattered electrons whose paths are not similarly affected. Because of this, it should be possible to obviate imaging problems due to charging by filtering the electrons used to form the image to backscattered electrons.

Other types of detectors exist such as through the lens detectors also called in lens detectors and detectors specifically devoted to backscattered electrons. The former detectors are typically associated with high resolution imaging using cold FEG electron beams and because of their line of sight location are able to resolve along hole walls oriented parallel to the beam geometry. The latter detectors comprise solid state detectors responding to electron impingement on a p-type semiconductor. These solid state detectors are divided into two or four parts. This is because the signals from each sector can be added or subtracted. In simple terms, in sum

Fig. 5 Secondary electron image of BaTiO₃ polycrystalline ceramic. Reproduced from Sturm, S., Jančar, B., 2014. Microstructure characterization of advanced ceramics. In: Shen, J.Z., Kosmač, T. (Eds.), *Advanced Ceramics for Dentistry*. Netherlands: Elsevier, pp. 151–172.

Fig. 6 Schematic of Everhart-Thornley detector. Reproduced from Joy, D.C., Howitt, D.G., 2003. Scanning electron microscopy. In: Meyers, R.A. (Ed.), *Encyclopedia of Physical Science and Technology*. Netherlands: Elsevier, pp. 457–467.

mode the signal returned relates solely to chemical differences in the specimen and images accordingly, whilst when the difference approach is employed the signal and thus image relates to surface topography. Thus the terms chemical or topographical imaging.

From the above descriptions relating to specimen beam interactions as well as electron emission and thus image formation, it should be clear, and thus appreciated when using scanning electron microscopy, that information captured may be derived from deeper in the sample than thought and the signal that arises from each point on the microscopes x-y raster can have come from a fairly large diameter area. Thus, it is always useful to think about what one is really looking at when using a SEM.

Factors Affecting Image Resolution and Apparent Quality

Probe or Beam Current

From Eq. (1), it is clear that low probe or beam currents should lead to smaller probe diameters and that smaller probe diameters should give better microscopic resolution. This is indeed true, and in addition, smaller probe currents result in less material damage which may be of importance when looking at bioceramic/bioglass tissue strictures or polymer derived ceramics and composites. Another useful factor to bear in mind for SEMs without sophisticated beam control (e.g. desktop systems) is the smaller the probe size, the less is the astigmatism effect and the easier it is to correct. Large beam currents are required for X-ray analysis, particularly if employing wavelength dispersive spectrometry (WDS). Otherwise, high beam currents give very good TV

Fig. 7 Ground polished and plasma etched cross-section of silicon nitride. Reproduced from Erauw, J.P., Gilissen, R., Sleurs, J., 1994. Gas pressure sintering of silicon nitride: the influence of additive type and sintering parameters on the microstructural development. Transactions of the Materials Research Society of Japan 14A, 879–882.

scan rate images with poor resolution. The writer would very strongly suggest that image quality is developed using slow scan rates with low probe currents so as to get the best image resolution.

Accelerating Voltage

Accelerating voltage, of course, controls the interaction volume (see Eq. (4)) and thus the interaction depth and radius. Thus, it controls the depth from which image information comes from. This can sometimes cause a problem with backscattered electron images of a low atomic number phase embedded in a high atomic number phase. Thus, while Fig. 7 shows excellent clarity of image for an etched sintered silicon nitride with silicon nitride grains clearly discernible from a surrounding yttrium-SiAlON glass, it is virtually impossible to obtain such a clear image of the same material in the as polished condition because of the interaction between the glass and silicon nitride signals in the surface layers which makes boundaries between the phases diffuse. By reducing the accelerating voltage such diffuseness is reduced due to the reduced sampling depth. Such factors can also interfere with the sharpness of topographical features and so the clarity of surface structures is enhanced at low accelerating voltages. The same is true for so-called edge effects. Thus, greater clarity of edge structures is realized at low accelerating voltages (see JEOL, 2020b). Low accelerating voltages cause less damage to specimens, particularly those with organic content. Despite the marked advantages of low accelerating voltages, SEM resolution is higher with greater accelerating voltages.

Working Distance

This distance, which is that between the surface of the objective lens and the top surface of the specimen, controls resolution and depth of field (i.e., the depth over which image clarity is maintained). Lowering working distances increase microscope resolution allowing higher magnification images to be collected. But, this is at the expense of the depth of field, meaning that only a part of the image may be in sharp focus. Longer working distances reduce image resolution while increasing depth of field. Incidentally, for X-ray analysis, geometry is important and therefore the exact working distance consistent with that geometry must be employed.

Objective Aperture

A large objective aperture is associated with high probe currents, low resolution and small depth of field. A small aperture is associated with the opposite effects i.e., high resolution, greater depths of field and smaller probe currents. As for probe current settings, TV scan rate images appear good quality with a large aperture but grainy with a small aperture. In general, many SEMs either set the objective aperture automatically depending on other microscope settings, or recommend an aperture setting again depending on microscope settings.

Other Factors

Specimen tilt may be employed to greatly improve imaging of surface roughness characteristics. Such tilt angles need be fairly slight (e.g., 5° – 15°) but significant improvements can be realized as show in JEOL (2020a). Contamination of a sample during imaging is extremely annoying unless one has the capacity to move the position of the image electronically as well as physically. JEOL (2020a) notes that gases in the microscope, albeit at very low pressure can be acted on by the electron beam and decorate the specimen surface in the scan area so that it appears dark. Specimen cleanliness is clearly very important as is the cleanliness of any mounting media, including double sided adhesive tapes (even if conductive) and conductive paints and inks. These media should be thoroughly dried prior to being placed in the SEM vacuum chamber. Improving specimen and mount/holder cleanliness

should markedly decrease contamination levels. The final factor is the compromising nature of specimen charging on image quality as indicated above. Charging is best ameliorated by using thin coatings of carbon, gold or palladium applied by sputter coating. However, it can be lessened by the use of low accelerating voltages, small probe currents and small working distances (see [He et al., 2018](#)) in addition to looking at filtering the electrons used for imaging as described above. [JEOL \(2020b\)](#) gives very good initial advice on the basics of specimen preparation, including coating.

Environmental SEM

As indicated in [Fig. 1](#), the pressure inside the electron microscope column is typically of the order of 10^{-5} Pa. The mean free path of electrons in this sort of vacuum exceeds 10 km. This is drastically reduced to 1.4 cm if the pressure is increased to 133 Pa and 100 times less if the pressure is 1330 Pa. Because of this data, it is not possible to have an electron beam column at high pressures or the beam would not reach the lens assemblies. Thus, it is necessary to find a way of having the SEM column assembly under a good vacuum and the sample under a substantially higher pressure. To facilitate low pressure SEM, also called environmental SEM (ESEM) or variable pressure SEM (VPSEM), pressure limiting apertures can be located in the beam path ([Donald, 2012](#)). These apertures allow the pressure to be increased from the high vacuum region in the filament and condenser lens regions to up to 2000 Pa in the region of the specimen. Having the specimen at raised pressure allows ready imaging of samples containing moisture or volatiles as well as the specimens which are non-conductive. Non-conductive specimens can be examined because of the charge neutralizing effects of gas ionization in the high pressure regions. Clearly, the distance between the pressure limiting apertures and the specimen must be consistent with the mean free path data so that the beam does not lose its sharp focus due to appreciable broadening by the higher pressure gas environment. In addition to the very good background given by [Donald \(2012\)](#), [Podor et al. \(2012\)](#) give excellent examples of the use of ESEM for such in-situ experiments as hydration, dehydration, swelling on moisture uptake etc.

Other Possibilities

Other imaging capabilities in the SEM are magnetic imaging (see [Joy and Howitt, 2003](#); [Goldstein et al., 2003](#)), cathodoluminescence imaging (see [Joy and Howitt, 2003](#); [Goldstein et al., 2003](#); [Szyrkowska, 2005](#)) and electrical imaging of circuits ([Goldstein et al., 2003](#)). [Jiang et al. \(2017\)](#) also show how electrical analysis of materials can be conducted with in-situ instrumentation in SEMs as well as how it is possible to look at tensile, compression, bending, and electrical property measurements on nano-scale features. In addition, the use of in-situ heating stages to follow transformations e.g., crystallization of glasses further extends the capability of SEM analysis.

X-Ray Analysis

Introduction

As described by [Llovet \(2019\)](#), when an electron beam enters a material characteristic X-rays are emitted from the interaction volume as well as those leading to background X-radiation. These X-rays have characteristic wavelengths (λ) and therefore energies (E), since $E \text{ (keV)} = 1.24/\lambda \text{ (nm)}$ and can be detected either by their energy or wavelength.

Energy Dispersive X-Ray Analysis

X-rays are sorted in terms of energy by energy dispersive spectroscopy systems (EDS systems). X-rays emanating from the specimen surface impinge on the surface of a lithium drifted silicon crystal and cause ionizations within the crystal creating electron hole pairs. A high voltage across the silicon crystal causes electrons to be transported to a field effect transistor and the original X-ray impingements yield voltage step outputs which are amplified to a suitable output signal via a pulse processor. Because of this system design, it is not possible for every X-ray pulse to be recorded and the fraction of events not recorded due to pulse pileup. This gives rise to deadtime which is defined as $(1 - (\text{output rate}/\text{input rate})) \times 100\%$. This deadtime value is controlled by the time constant for the pulse processor and the beam current used in the SEM. Values in the range 10%–50% deadtimes are suggested as being suitable for analysis. However, high deadtime rates due to pulse processor settings affect the position and intensity of the carbon X-ray peak as shown in [Goldstein et al. \(2003\)](#). For high deadtimes the peak moves to lower energies and higher intensities. Experimentation by the writer shows that this artifact is only apparent if the pulse processor settings are used to increase deadtime. Increasing deadtime by increasing beam current and thus X-ray yield does not induce the artifact. This writer has always preferred to use low deadtimes (10%–20%) for qualitative and quantitative X-ray analysis by EDS.

[Fig. 8](#) shows the energies of K_{α} , L_{α} and M_{α} X-rays as a function of atomic number. It is clearly seen that over a wide range of energies, K_{α} radiation and L_{α} radiation have the same energies and so it may well be possible that two elements may emit X-rays with the same energy, although one emits K_{α} and the other L_{α} radiation. The same can be said for K_{α} , L_{α} and M_{α} albeit over a lower energy range. Because of this information, it is important to realize that characteristic X-ray energies and therefore peaks can overlap. A typical example is the overlap of Ti K_{α} and Ba L_{α} peaks as shown in [Fig. 9](#). Not only do α radiation peaks arise, β , γ and ξ peaks also arise and these can cause overlaps too. The most common overlaps are listed in [Table 4](#). These overlaps can cause problems in identifying unknowns in specimens and so it is always very useful to look at the uniformity in peak shapes i.e., they should be symmetrical. If they are not, then the

Note: After Goldstein, J., Newbury, D.E., Joy, D.C., *et al.*, 2003. Scanning Electron Microscopy and X-Ray Microanalysis, third ed. US: Springer.

major peak may well be hiding an X-ray signal from an overlap element. It is also useful to know the relative intensities of the α , β , γ peaks too. Hafner (2020) gives the following data for the relative intensities: $K_\alpha: K_\beta = 10: 1$; $L_\alpha: L_{\beta 1}: L_{\beta 2}: L_\gamma = 10: 7: 2: 1$; $M_\alpha: M_\beta = 10: 6$. Thus, for example if a K_β peak appears to have a greater intensity than 10% of a corresponding K_α peak then there is a probable overlap. In addition to overlaps, two types of counting artifacts can arise. These are sum peaks and escape peaks. The former arise when two X-rays impinge on the detector at nearly the same time and are recorded as one with twice the energy. The latter occurs when the analyzing crystal creates an X-ray itself which results in a loss of X-rays at 1.74 keV below the characteristic energy of the elements highest intensity peak. The writer has been amused on occasion when students have reported argon containing alumina in lab reports. This erroneous conclusion arises from the sum peak for Al appearing at the same energy as Ar K_α X-rays!!!.

Wavelength Dispersive X-Ray Analysis

X-rays can also be sorted by wavelength, as indicated previously. This detection is done using X-ray diffraction theory. Rather than X-rays of known wavelength being diffracted by a crystal of unknown crystal spacing to yield a diffraction angle, X-rays emitted by a specimen in a SEM are diffracted by a crystal of known interplanar spacing to generate a diffraction angle which can then be related to the element giving rise to the X-ray. A typical set up is shown in Fig. 10. Typical crystals with their associated crystal spacings are: thallium acid phthalate (TAP $2d = 25.76 \text{ \AA}$), pentaerythritol (PET $2d = 8.74 \text{ \AA}$), and lithium fluoride (LiF $2d = 4 \text{ \AA}$).

Fig. 10 Geometry of wavelength dispersive spectrometer (WDS) Reproduced from Llovet, X., 2019. Microscopy: Electron probe microanalysis. In: Worsfold, P., Townshend, A., Poole, C., Miro, M. (Eds.), *Encyclopedia of Analytical Science*, third ed. Netherlands: Elsevier, pp. 30–38.

Fig. 11 Comparison of resolution of WDS and EDS X-ray analysis of InSb plotted on a common energy axis. Reproduced from Llovet, X., 2019. Microscopy: Electron probe microanalysis. In: Worsfold, P., Townshend, A., Poole, C., Miro, M. (Eds.), *Encyclopedia of Analytical Science*, third ed. Netherlands: Elsevier, pp. 30–38.

Others with larger crystal spacings are available and vary depending on manufacturer. For each crystal there is a range of elements whose X-ray wavelengths will be compatible with the analysis geometry for the specific crystal spacing.

WDS or EDS?

The advantage of EDS is that it is a very quick method of obtaining an overall chemical analysis of a material across the whole range of elements from B to U. Limits of detection for EDS systems vary depending on manufacturer, but are generally about 0.1% for the transition elements. Detection limits for WDS systems are much better with 0.01% limits being realized for low atomic number elements. In addition, WDS systems do not suffer from peak overlaps because of the much better X-ray resolution as shown by the comparison of peak widths in Fig. 11.

Uses of X-Ray Analysis

The use of X-ray analysis extends to 4 possible uses: (1) qualitative analysis, (2) X-ray maps indicating the spatial distribution of elements within a field of view (see Cookman and Bangert (2021)), (3) Line profiles i.e., intensity – distance profiles across layers

and interfaces and (4) quantitative analysis. For each of these, the operator and reporter of results must appreciate the depth and radius of the electron beam interaction zone. This can be considerable, as discussed above, and so qualitative or quantitative analysis of even a 500 nm particle in a totally dissimilar matrix will yield analyses containing matrix elements. It is of great importance that the operator and reporter of results acknowledges the type of microstructure they are analyzing in the light of the background physics.

Care needs to be exercised when making quantitative analyses as indicated by Goldstein *et al.* (2003), Llovet (2019) and Hafner (2020). This is because quantitative X-ray analysis needs to take into account the effects of atomic number (Z), X-ray absorption (A) and X-ray fluorescence (F) on the generation and escape of X-rays to and from the specimen surface. This means that apparent concentrations of each element must be corrected by a ZAF correction to get accurate data. An equally accurate approach is the use of a phi-rho-Z correction routine (see Goldstein *et al.*, 2003) used by the various EDS equipment suppliers. When carrying out quantitative analysis using EDS, it is important that the total number of counts in the spectrum exceeds at least 0.25 M counts and to ensure that a calibration standard has been analyzed in the not too distant past.

Characterization of Ceramic Microstructures

Rohrer (2014) has prepared a comprehensive review of methodologies for characterizing ceramic microstructures. This work looks in depth at electron backscattered diffraction and how it can be used to characterize grain size, grain orientation, definition of grain boundary types etc. as well as misorientation angles. It is strongly recommended that researchers read the article by Rohrer (2014) and use it as a key text to underpin their ceramic characterization approach.

A Note on Information Sources

This chapter has been written on the basis of three lectures given to Master of Science and 1st year Ph.D. students. These lectures were based on the list of material given in the reference list as well as 40 years experience using SEM systems and working with SEM engineers and demonstrators as well as excellent technicians. Because of this, this chapter makes reference to specific texts only when appropriate. Elsewhere the text is based on knowledge accumulated from the various sources mentioned.

Fractography: Brittle Materials

John J Mecholsky Jr., University of Florida, Gainesville, FL, United States

© 2021 Elsevier Inc. All rights reserved.

Introduction

Quantitative fractography or fracture surface analysis (FSA) is the application of fracture mechanics to characteristic features on the fracture surface. FSA can identify the cause of failure, the amount of residual stress, if any, on the surface during fracture, and the existence or not of environmental slow crack growth before catastrophic failure. Thus, quantitative fractography is an essential tool used in failure analysis of components that fracture in a brittle manner. For convenience the term “brittle material” will be used to mean a material that fails in a brittle manner in the environment which results in that behavior. Fractography can be used to not only identify the source of failure, but also determine whether the failure is caused by a processing defect or by an overload on the component.

General Appearance of Fracture Surfaces

In general, brittle fracture for quasi-static loading results in one primary failure origin (Danzer *et al.*, 2008). The location of that origin is at the largest crack or flaw in the highest stressed region. The crack at the origin propagates approximately perpendicular to the principal tensile stress (alternatively, where K_{II} is zero) in an unstable manner and for a uniform stress field, radiates out in an approximately symmetric manner from the origin (Fig. 1) (Freiman and Mecholsky, 2019). Due to thermal vibrations, a distribution of bond strengths and an irregular crack front, the propagation of the crack does not occur on one plane. The crack immediately leaves the plane perpendicular to the applied stress direction at specific points along the crack front. At the start of the fracture process along the crack front, the individual bonds either act in concert and increase in amplitude, or subside, depending on entropic considerations. The number of points of departure depends on the amount of energy supplied in the fracture. If a small amount of energy is supplied, i.e., low stress fracture, then there are few points of departure initially, and the “plane” of propagation appears relatively smooth. If there is a large amount of stored strain energy before fracture, i.e., a high stress fracture, then there are many points of departure and the fracture surface appears rough near the origin (Kulawansa *et al.*, 1994). Note that these departures from the plane initially have amplitudes smaller than the wavelength of light and would appear smooth under the optical microscope.

During loading, strain energy is stored in the material. The stored strain energy is released during propagation. When the creation of surface, the release of particles, the rise in temperature and all other processes occurring during crack propagation are not great enough to satisfy the release of the stored strain energy, the main crack branches into two or more branches (Fig. 2). If there is a supply of strain energy, the process will continue until either there is no more material to fracture or the energy is dissipated and the crack arrests.

The techniques associated with fractography and the identification of features are well established (Quinn, 2016). Excellent presentations of the principles of fractography can be found in the ASTM Standard C, 1322-15 (2015) and the US Army Military handbook MIL-HDBK-790 (1992). The fractographic principles apply to all classes of materials, i.e., ceramics, metals, or polymers. As an example, Fig. 3 shows the fracture surface of a large grained ZnSe. For large grained materials, the features are often difficult to observe because of large, local crack deflections in the direction of easy propagation of grain facets or boundaries. These large deflections mask the more subtle mist and hackle markings (Beauchamp, 1996). Usually, this difficulty is compensated for because most large grained materials fail in a transgranular manner and leave classic characteristic markings on the surface, e.g., cleavage marks, “river” lines and twist hackle indicators (Fig. 3) (Frechette, 1990). The river marks (twist hackle) result from the propagating crack deflecting onto parallel planes in local, adjacent regions along the crack front (Rossmanith, 1980). These regions also result in cleavage “steps”. This chapter addresses the sources of failure in materials that fracture in a brittle manner and the quantitative analysis of the resulting fracture surfaces.

Sources of Failure

Fracture in brittle materials occurs due to the application of stress to a flaw in the material such that the combination of stress and size of flaw leads to unstable propagation of that defect. In this context, flaw, crack, and fracture origin are used interchangeably. Almost all materials have “flaws” due to fabrication, manufacturing or preparation. Use of the word “flaw” here does not imply a defect in the material, it is a naturally occurring result of fabrication and surface treatment of components. Most origins of fracture in brittle materials such as glass start from cracks, whose radii are atomically sharp and tend to be effectively 2-dimensional, i.e., their opening is of the order of angstroms or nanometers if unstressed (Mecholsky *et al.*, 1974). Even when the source is an inclusion of foreign material, the fracture generally originates from a crack at the boundary between the bulk material and the inclusion. Pores can act as a source of failure and are not as severe as a sharp crack. When pores act as a source of failure they are much larger than any sharp crack in the same stressed region.

Fig. 1 Fracture surface of a silica glass fiber showing fracture origin, mirror, mist and hackle regions. The origin is a crack at the surface created by the thermal expansion difference between the fiber and the foreign “dust” particle attached to it while the fiber was still hot during fabrication.

Fig. 2 Crack branching patterns in magnesium fluoride disks failed in ring-on-ring biaxial flexure. Arrows indicate origin of fracture. Failure stresses are: #10–47 MPa; #16–60.2 MPa; #17–86.9 MPa; # 7–91.5 MPa.

The shape and size of cracks are important to the fracture process, so it is necessary to understand and to investigate their sources and characterization. The types of sources can be categorized by their origination: extrinsic and intrinsic. Extrinsic origins include mechanical (handling, intentional and unintentional indentation, finishing operations, impact damage, etc.) and chemical and thermal processing and treatment (sputtering, etching, quenching, thermal shock, etc). Intrinsic origins include defects in the structure inherent in the specific fabrication or manufacturing technique such as sintering which can lead to low density regions or extrusion which can lead to non-uniform grains. Fracture origins may be characterized by their identity, location and size. Fracture origins may be volume flaws such as internal cracks, pores, agglomerates, inhomogeneous density or compositional regions, or surface origins such as cracks due to machining, surface pits or voids and impact damage due to handling ([Mecholsky and Freiman, 1979](#)). Of course, a volume-type defect can be located at the surface and a material can contain both surface and volume flaws. The location can be at the surface, in the volume, near the surface and/or at the edge of a component ([Quinn, 2016](#)).

Fig. 3 Fracture surface SEM images of large grained ZnSe. The white arrows on the ZnSe surface show one end of a semi-elliptical crack from a polishing striation (thin white arrow) growing to the larger crack boundary (second, thicker arrow) before catastrophic failure. The black arrow shows an example of twist hackle (“river marks”) on a large single grain.

Quantitative Analysis

Almost all of the mechanically induced cracks can be idealized as a semi-elliptical, sharp crack of depth, a , and half-width, $2b$ (Randall, 1967; Quinn and Swab, 1996). The relationship between the stress at fracture, or strength, σ_f , and the fracture toughness, K_{IC} , is:

$$K_{IC} = Y\sigma_f(c^{1/2}) = \sqrt{(2E'\gamma_c)} \quad (1)$$

where K_{IC} is the critical stress intensity factor (fracture toughness) and Y is a geometric factor which accounts for the shape and location of the fracture-initiating crack, E' is E , the elastic (Young's) modulus for plane stress conditions, and $E' = E/(1 - \nu^2)$ for plane strain conditions where ν is Poisson's ratio, and γ_c is the critical fracture energy, i.e., all the energy involved in fracture including the creation of new surface. The quantity Y in Eq. (1) depends on the ratio a/b (Randall, 1967). However, the crack size can be approximated by an equivalent semi-circular crack size, c [$c = (a * b)^{1/2}$]. This approximation allows many irregular crack shapes to be analyzed and avoids the complications of calculating a geometric factor for each crack (Freiman and Mecholsky, 2019). For surface cracks without local residual stress and those that are small relative to the thickness of the sample, $Y \sim 1.26$ (Scherrer et al., 1999). Three-dimensional defects such as pores, pits or inclusions need special considerations (Quinn, 2016).

We observe that from the fracture origin, the crack propagates in a relatively smooth plane (the mirror region) to the boundary, r_1 , and progressively gets rougher by deviating slightly out of plane in a region that resembles mist (the mist region), between r_1 and r_2 . Finally, the crack deviates locally from the main plane of fracture (the hackle region), between r_2 and r_3 , getting very rough and finally branching into two or more cracks at r_3 . Beyond macroscopic crack branching, the process can repeat itself on each branch of the propagating crack (Quinn, 2016; Freiman et al., 1991). These regions are all related to the applied (far field) stress at fracture, σ_f :

$$\sigma_f r_j^{1/2} = \text{constant} = K_{Bj} / Y'(\theta) \quad (2)$$

where $r_j = r_1, r_2$ or r_3 corresponding to the different regions in an analogous equation to Eq. (1). K_{Bj} is the crack branching stress intensity and $Y'(\theta)$ is a crack border correction factor where θ is the angle from the surface to the interior, i.e. $\theta = 0-90^\circ$. Note that K_{Bj} is proportional to K_{IC} , i.e., $K_{Bj} = \lambda K_{IC}$ where λ is 3–5 (for $j = 1$) for most ceramic materials (Kirchner and Conway, 1988; Kirchner and Kirchner, 1979; Bradt, 2011a, 2011b). Table 1 lists values of characteristic constants for many ceramics. Fig. 4 shows the strength of silica glass versus the fracture mirror radius, r_1 , for fibers loaded in tension and bending, for disks loaded in biaxial tension and for bars loaded in three point flexure (Freiman and Mecholsky, 2019). The straight line is the graphing of Eq. (2). The fact that the relationship represented by Eq. (2) is valid for several stress states during failure provides increasing confidence that this equation is useful in analyzing in-situ field failures. Also, notice the large range of stress values and of sizes of fracture mirror radii.

Fractographic Procedures

The fracture origin can be determined by looking on the fracture surface and tracing the telltale markings back to the origin. These markings include twist hackle (river marks), fracture tails, cleavage steps, Wallner lines, and branching locations. Wallner lines are

Fig. 4 Fracture Stress versus Fracture Mirror Radius, r_1 , for optical fibers and bulk silica. The solid line is a linear least squares fit with slope = -0.5 [Eq. (2)]. Solid data from Maurer, R.D., Miller, R.A., Smith, D.D., Trondsen, J.C., 1974. Optimization of Optical Waveguides Strength Studies. Final technical rept. NY: Corning Glass Works. Mecholsky, J.J., Rice, R.W., Freiman, S.W., 1974. Predictions of fracture energy and flaw size in glasses from mirror size measurements. J. Am. Ceram. Soc. 57 (10), 440–444.

the result of intersections of the crack front with a propagating elastic stress wave initiated from another source, such as the surface, an inclusion, or secondary crack. Wallner lines can be used to calculate the velocity of a crack front (Quinn, 2016).

The general fractographic procedure is outlined in ASTM Standard C1322–15 or the National Institute of Standards and Technology (NIST) WebPages [See Relevant Website Section] (Quinn, 2016). When characterizing fracture origins, photographs of the overall sample, of the fracture mirror and surrounding regions including the branching locations, if applicable, and of an enlargement of the fracture origin region should be made. Since there is a distribution of crack sizes on any component, there is a corresponding distribution of strengths. The strength and flaw size distributions have been found to follow Weibull statistics. In addition, in the cases where strength values can be obtained independently, it is useful to correlate the strength distribution probability with the flaw location, size and identity. The strength distribution, i.e., the probability of failure versus the strength, can be obtained using a Weibull analysis as outlined in ASTM standard C1239–13 (2013). A testing procedure for strength can also be obtained by following ASTM Standard C, 1161 (2018). To be complete in fractographic analysis when it is possible to obtain many strength samples, a fractographic montage should be attached to the Weibull probability graph. The fractographic montage consists of sketches or photographs of the fracture origins with arrows pointing to the location on the probability of failure-strength curve (Quinn, 1987).

Global Residual Stress

Near-surface residual stresses, σ_r , can greatly affect the performance of materials. If these global stresses are tensile ($+\sigma_r$), then the effective strength of the material is reduced. If the global near-surface stresses are compressive ($-\sigma_r$), then this often leads to superior mechanical performance. Quantitative fractography can be used to evaluate the magnitude of these global residual stresses in post-mortem analysis. Eq. (2) can be modified to include the effect of residual near-surface stresses, σ_R :

$$\sigma_c r_1^{1/2} Y(\theta) = +K_{Bj} - \sigma_R r_1^{1/2} Y_R(\theta) \quad (3)$$

where $Y_R(\theta)$ is a crack border correction factor for the residual stresses and usually assumed to be 1 and the other symbols are as described above (Conway and Mecholsky, 1989). A graph of the left side of Eq. (3) versus a selected value of r_1 , e.g., r_2 , for several samples will result in data which have either a zero slope, i.e., no residual stress, or a slope related to σ_R (Fig. 5). For individual components, the expected applied stress for samples without residual stress can be estimated from Eq. (1) after measuring the crack size or from Eq. (2) after measuring the mirror radius. Thus, the mirror-to-flaw size ratio on the surface will be the same as without residual stress. However, the shape of the mirror-mist border will be quite different. An example of this shape difference is illustrated in Fig. 6. Fractographic procedures can be combined with other techniques, such as finite element analysis (FEA) and closed form solutions of thermal mismatch, to verify the calculations of global residual stresses (Aboushelib et al., 2008).

Local Residual Stress

A typical crack may experience other components of residual stress, such as local residual stress from the creation of the crack from impact or contact events (Lawn and Marshall, 1991). Such is the case for deformation induced surface cracks produced in sharp-point contact. In these cases, $Y = 1.65$ in Eq. (1) (Marshall et al., 1980). The mirror-to-flaw size ratio for cracks with local residual stress is:

Fig. 5 Graph of Eq. (3) to determine global residual stress. The triangles represent annealed soda-lime silica glass and the diamonds represent tempered soda-lime silica glass. Tempering is a thermal-quench process which results in compressive stresses on the external surfaces of glass components. r_2 = the radius of the mist-hackle boundary. This graph indicates that there is an 82 MPa (compressive) residual stress on the tempered glass surface.

Fig. 6 Schematics of fracture mirror boundaries for materials fractured in a flexure mode. (Upper) – Fracture mechanics approach. Eq. (2) explains the inward curvature at the surface and the opening of the mirror toward the interior due to lessening of flexural stresses. (Lower) – Fracture mechanics approach. Eq. (3) can explain the shape of the mirror boundary in the presence of residual compressive stress. The critical crack size is the same in both examples.

$$r_i/c = [4 Y K_{Bj}/3 Y(\theta) K_{IC}]^2. \quad (4)$$

The value of r_i/c for cracks without local stress removes the factor $(4/3)^2$ (Marshall *et al.*, 1980).

Slow Crack Growth

In many cases environmental effects can affect the fracture of components. For example, slow crack growth can occur due to stress enhanced chemical reactions at the crack tip (Michalske and Freiman, 1983). These reactions cause the initial crack to grow slowly before catastrophic failure. At the time of failure, the mirror radius-to-critical crack size ratio is the same as for the condition of annealed, stress-free material. However, the mirror-to-initial crack size is a function of time under load. Thus, if the mirror to crack size is greater than about 20:1, then more than likely some slow crack growth had occurred before fracture (Mecholsky *et al.*, 1979). In some cases, it becomes very obvious that crack growth has occurred before rapid failure (Michalske, 1979; Mecholsky, 1981). There are markings on the surface that indicate the crack boundary before rapid fracture. In other cases, it is not obvious, but the crack size to mirror size ratio will indicate that there must have been slow crack growth due to a stress enhanced chemical process.

Fig. 7 The toughness of type A Si_3N_4 displays “R” curve behavior.

R-Curve Determination Using Quantitative Fractography

Materials containing microstructural features such as elongated grains, transformation phases, stress induced microcracking, fibers, or multiple grain sizes can exhibit a phenomenon known as a rising R-curve (Resistance-curve) behavior, i.e., an increased resistance to crack growth with increased crack size (Munz, 2007). Although the mechanisms around the crack tip can be different, the overall result is a toughness-crack size curve that is not constant, but increases with increasing crack size up to a limit at which point the resistance becomes constant. Typically, stable crack growth specimens are used to measure the toughness or crack growth resistance parameter as a function of crack size. Both compact tension, double cantilever beams and 3-point flexure technique using a notched beam with sharpened starter crack have been used (Moon *et al.*, 2000; Kruzic *et al.*, 2008; Steinbrech, 2005).

The determination of R-curve values can also be obtained using quantitative fractography. The strength of fractured flexure bars can be recorded and the size of the fracture initiating crack can be measured. Thus, the fracture toughness can be calculated using Eq. (1). If there is no R-curve behavior using small crack specimens such as flexure bars, then the calculated values will be the same for all crack sizes. If there is R-curve behavior, then the calculated values will increase with increased crack sizes up to a certain size. These measurements agree with the larger crack size techniques. An example of such R-curve behavior is shown for polycrystalline silicon nitride in Fig. 7. In this case, the mechanism of increased toughness with increasing crack size is grain-to-grain interlocking of the elongated grains in the microstructure, i.e., crack bridging (Mecholsky *et al.*, 2002).

Mixed Mode Fracture

Although there has been much study on the fracture of brittle materials in mixed-mode loading, to date, all studies on fractography were focused on surfaces failed from surface cracks in pure tension or pure mode I. In the past, there was little, if any, literature on the quantitative fractographic study of fracture surfaces failed in combined tension and shear (mixed-mode) loading (e.g., Freiman *et al.*, 1979). More recently, research analyzed the features of fracture surfaces failed in external mixed mode (I/II) loading. This research determined there were some distinguishing fracture surface characteristic markings due to mixed-mode loading (Gopalakrishnan and Mecholsky, 2012).

The analytical expressions for the stress intensity factors (SIF) for surface flaws under mixed-mode loading conditions has been well-established in the literature and are given by (Shetty *et al.*, 1987):

$$K_I = Y_I M_I \sigma \sqrt{c} \sin(2\theta) \quad (5)$$

$$K_{II} = Y_{II} M_{II} \sigma \sqrt{c} \sin \theta \cos \theta \quad (6)$$

where σ is the applied stress, c is the critical flaw size given by Eq. (1), Y_I and Y_{II} are the geometric constants and M_I and M_{II} are free surface correction factors. Similar equations apply for the SIFs for both as-indented and annealed samples in the case of glass ceramics as opposed to non R-curve materials, wherein the effect of residual stress needs to be accounted for in the as-indented samples. For a semi-circular surface flaw, the geometric constant, Y_I is given by (Smith *et al.*, 1967):

$$Y_I = 2\sqrt{\pi} \quad (7)$$

Kassir and Sih (1966) developed the expression for K_{II} for penny-shaped cracks with the geometric constant Y_{II} given by:

$$Y_{II} = 4\sqrt{\pi(2-\nu)} \quad (8)$$

The critical mode I SIF, K_{IC} can be determined from Eq. (9).

$$K_{IC} = Y_I M_I \sigma_c \sqrt{c} \quad (9)$$

where σ_c is the critical stress for pure mode I loading. Studies conducted by Randall (1967) and other researchers (e.g., Shetty *et al.*, 1987; Scott and Thorpe, 1981) agree that the correction factor is within 10%–12% for surface cracks. Smith and Sorensen (1974) have shown that the values of M_{II} are approximately equivalent to M_I for equivalent crack sizes and shapes. The ratio M_{II}/M_I is usually taken to be unity. Thus, once the applied stress and the flaw dimensions are measured, the SIFs can be calculated from

Eqs. (5) and (6). Once K_I and K_{II} are determined, then it is a matter of selection of the appropriate theory for combining K_I and K_{II} . We assume that when $K_C = K_{IC}$, fracture will occur for an angled crack. However, it is not well-established in the literature which method is the correct one for combining K_I and K_{II} .

The most popular theories to combine K_I and K_{II} to determine K_C are presented below.

The non-coplanar strain energy release rate (NCSERR) criterion assumes that crack growth starts at a critical value of the strain energy release rate (SERR) in a direction along which the SERR is maximum. An analysis based on the maximum SERR was first performed by Hussain *et al.* (1974). They analyzed the non-coplanar crack extension of inclined cracks based on Griffith energy balance. The condition for fracture under mixed-mode loading in this case is given by:

$$K_C = K_I [b_{11} - b_{12}(K_{II}/K_I) + b_{22}(K_{II}/K_I)^2]^{1/2} \times [(1 - (\gamma/\pi))/(1 + (\gamma/\pi))]^{\gamma/2\pi} \quad (10)$$

$$b_{11} = 4(1 + 3 \cos^2 \gamma) / [(3 + \cos^2 \gamma)^2] \quad (11)$$

$$b_{12} = 32 \sin \gamma \cos \gamma / [(3 + \cos^2 \gamma)^2] \quad (12)$$

$$b_{22} = 4(9 - 5 \cos^2 \gamma) / [(3 + \cos^2 \gamma)^2] \quad (13)$$

The combination of K_I and K_{II} results in effective mixed-mode fracture toughness and is given by K_C as shown in Eq. (10).

Erdogan and Sih (1963) hypothesized that fracture commences at the tip of the crack in a radial direction and crack growth occurs in the plane which is normal to the direction of maximum tensile stress (MTS). This hypothesis implies that crack growth starts at a critical value of the tangential stress along the direction of maximum tangential stress. The tangential stress in the neighborhood of the crack tip, in cylindrical coordinates, is given by:

$$\sigma = [1/\sqrt{(2\pi r)}] \cos(\gamma/2) [K_I \cos^2(\gamma/2) - 1.5 K_{II} \sin \gamma] \quad (14)$$

The MTS criterion can be expressed as:

$$\partial \sigma / \partial \gamma = 0 \text{ at the crack turning angle, } \gamma \quad (15)$$

The angle γ at which the tangential stress reaches a maximum value can be evaluated in terms of K_I and K_{II} which is used to derive the general expression for mixed-mode fracture, given below.

$$K_C = K_I \cos(\gamma/2) [\cos^2(\gamma/2) - 1.5 K_{II}/K_I \sin \gamma] \quad (16)$$

Eq. (16) represents the conventional MTS criterion.

The critical strain energy release rate (CSERR) criterion states that crack growth starts along the initial crack plane when the SERR reaches a critical value, leading to the relation below:

$$K_C = K_I [1 + (K_{II}/K_I)^2]^{1/2} \quad (17)$$

Sih (1974) proposed that crack growth starts at a critical value of strain energy density (SED), S_{crit} , and propagates in the direction of minimum SED (MSED). The S_{crit} value was postulated as a material constant and hence it could be used as a measure of the fracture toughness of the material under mixed-mode conditions. Based on this concept an effective fracture toughness K_C can be derived as:

$$K_C = [8(a_{11} K_I^2 + 2a_{12} K_I K_{II} + a_{22} K_{II}^2)]^{1/2} \quad (18)$$

$$a_{11} = [(3 - 4\nu - \cos \gamma)(1 + \cos \gamma)]/16 \quad (19)$$

$$a_{12} = [\sin \gamma (\cos \gamma - 1 + 2\nu)]/8 \quad (20)$$

$$a_{22} = [4(1 - \nu)(1 - \cos \gamma) + (1 + \cos \gamma)(3 \cos \gamma - 1)]/16 \quad (21)$$

where ν is the Poisson's ratio of the material.

The crack size, c , to mirror size, r , ratio can be calculated for all crack angles in mixed-mode loading for small cracks in flexure by combining Eqs. (1) and (2). We then obtain:

$$c/r = (K_c/K_{Bj})^2 (Y_2/Y_c)^2 \quad (22)$$

where K_c is determined using the appropriate mixed mode theory. K_c/K_{Bj} can be determined experimentally.

A typical fracture surface of a soda-lime-silica glass fractured in mixed-mode (I/II) loading is shown in Fig. 8 (Gopalakrishnan and Mecholsky, 2012). Compare this image to that in Fig. 1. We notice there is no mist region and we can see that the hackle markings appear as lances. Such lance like features are thought to be generated due to the influence of mode I and mode III stress intensities acting along the crack front (Pons and Karma, 2010). The schematic of the typical features on a mixed-mode fracture surface in Fig. 9 is compared to the features on mode I fracture surface in Fig. 8. The reason for the lance hackle markings can be explained by the presence of a Mode III component at the tip of the crack. Pons and Karma (2010) show that in a local mixed-mode (I-III) loading condition, a "flat parent crack segments into an array of daughter cracks that rotate toward a direction of maximum tensile stress". They refer to these daughter cracks as "lances", clearly the same as the twist hackle markings observed in Fig. 8. They further explain that their calculations imply that the creation of the twist hackle features depends on both the applied

Fig. 8 Fracture surface of mixed mode fracture in a soda-lime-silica glass. Notice the absence of the mist region.

Fig. 9 Schematic of a fracture surface broken in mixed mode loading. Notice the absence of the mist region.

shear stress and the energy release rate. This would agree with the findings of [Gopalakrishnan \(2011\)](#) that the stress intensity at branching is a constant at the beginning of the microscopic twist hackle features. Other work has also shown that far field mixed mode (K_I – K_{II}) loading can result in a Mode III shear component at the tip of the crack ([Erdogan and Sih, 1963](#)). Higher order stress intensity terms at the crack tip become significant for mixed mode conditions ([Williams and Ewing, 1972](#); [Ueda et al., 1983](#)).

It has been difficult in the past to determine the appropriate mixed-mode theory to use to determine the fracture toughness for materials loaded on mixed mode loading. However, a more recent study by [Gopalakrishnan \(2011\)](#) suggests that the MSED theory appropriately describes mixed mode fracture, at least for R-curve materials. The author compared the four theories listed above for Macor® glass ceramic. The only theory that merged as one relationship was the MSED theory as shown in [Fig. 10](#).

[Mecholsky et al. \(1977\)](#) have shown that c/r is directly proportional to the fracture toughness. Thus, for an R-curve material where the fracture toughness is a function of the crack length, c/r values should increase with increasing crack length. The crack to mirror size ratio (c/r) as a function of the crack length, c for the different crack orientations in mixed-mode fracture is shown in [Fig. 11](#) for the Macor glass ceramic (MGC). The R-curve behavior of MGC ([Gopalakrishnan and Mecholsky, 2013](#)) is mimicked in the c/r versus c plot for the different crack orientations. This is contrary to the constant values of c/r obtained at a particular crack orientation for non or flat R-curve materials. The variation of c/r with crack length at a particular crack orientation for the MGC is due to the crack bridging mechanism which leads to the increasing resistance to crack growth with increasing crack extension. Although the raw data for c/r versus crack size will yield different curves for each crack orientation, if we use [Eq. \(22\)](#) to calculate c/r with the K_c values determined using [Eq. \(18\)](#), all the values for each angle at a particular crack size essentially over-lap ([Fig. 11](#)). This collapsing of the c/r graph further supports the MSED theory for use in determining the effect of mixed mode loading. In pure mode I loading, at $c > 150 \mu\text{m}$ when the fracture toughness of MGC reaches a steady value, the value of c/r is found to be approximately a constant (~ 0.15) and the value of c/r for $c > 150 \mu\text{m}$ increased to ~ 0.42 for $\theta = 45^\circ$.

Fractal Geometry

Fractal geometry ([Mandelbrot, 1982](#)) is being used in many fields of materials science, physics, chemistry and engineering because it can be applied to describe shapes and processes that are non-linear and seemingly complex. Fractal geometry is a non-Euclidean geometry which exhibits self-similarity (or self-affinity) and scale invariance. Self-similarity and scale invariance are characteristics

Fig. 10 Fracture toughness as a function of crack size demonstrating R-curve behavior in Mode I and Mixed Mode Loading. The only mixed mode theory that merges all the angles in mixed mode loading is the Minimum Strain Energy Density (MSSED) theory. Reproduced from Sih, G.C., 1974. Strain-energy-density factor applied to mixed mode crack problems. *Int. J. Fract.* 10, 3057–321. Gopalakrishnan, K., 2011. Mixed Mode Fracture in Brittle Materials. PhD Dissertation. University of Florida. Available at: <https://ufdc.ufl.edu/UFE0043736/00001>.

Fig. 11 Crack size to mirror size ratio as a function of the crack size. Notice that the relationship is constant regardless of Mode I or mixed mode loading.

of (scaling) fractals. A self-similar surface is one in which the length scaling is isotropic, i.e., one feature on the surface has a similar shape to another feature on the surface in any direction. A self-similar object remains invariant under the transformation $(x,y,z) \rightarrow (ax,ay,az)$ where a is a scalar constant. Typically, self-similar structures are also scale invariant, i.e., the features are not only similar in different regions, but also similar at different magnifications. A self-affine object is one which remains invariant under the transformation $(x,y,z) \rightarrow (ax,ay,az^\zeta)$ where ζ is called a roughness exponent. Fracture is one of the phenomena that has been modeled using fractal geometry (Russ, 1996).

Fundamental relationships can be derived between the fractal dimensional increment, D^* , and the fracture toughness of a material in the form of the critical stress intensity factor, K_{IC} :

$$K_{IC} = E a_0^{1/2} D^{*1/2} = Y(\theta) \sigma_f c^{1/2} \quad (23)$$

where E is the Young's modulus and a_0 is a parameter having the units of length. The relationship between K_{IC} and D^* is based on experimental observations (Fig. 12) and the relationship between K_{IC} and c is based on fracture mechanics and experimental confirmation. The measurement of D^* is an average property of the entire fracture surface and a measure of its tortuosity. The flaw size is a linear measure of the critical flaw area locally around the fracture origin. Fig. 1 shows a fracture surface depicting the origin and the surrounding tortuous topography.

It can be shown (Mecholsky and Freiman, 1991) that:

$$r_1/c = 1/D^* \quad (24)$$

The agreement of experimental data with Eq. (24) (Fig. 13) implies that there is scaling between the crack size and the point of branching. Furthermore, Eqs. (1) and (2) show that the ratio of the energy of crack initiation to that of crack branching is related to r_1/c ; there is also scaling between the energy of crack initiation and of crack branching. Thus, analyzing considering an energy scaling or a structural (geometric) scaling are equivalent. Moreover, the scaling is linear in energy or geometry. Passoja (1988) has suggested that this scaling is a general phenomenon that is observed in many materials and is related to the atomic structure.

Fractal dimensions for fracture surfaces of glasses, ceramics, glass-ceramics, single crystals, intermetallics and polymers have been measured (Mecholsky, 1996). Atomic force microscopy studies have shown that the fracture surface is not smooth at the

Fig. 12 Fracture toughness vs. Fractal dimensional increment, D^* . Data fall into material “families”, i.e., single crystals and large grain materials, glass ceramics, and fine grain polycrystalline materials.

Fig. 13 Mirror-to-crack size ratio (r_1/c) as a function of the Fractal Dimensional Increment, D^* .

atomic level for many materials and has the same tortuosity at the atomic level as at the macroscopic level. Thus, the crack front is neither smooth nor continuous. A fundamental relationship between basic materials constants, fractal geometry, and fracture parameters has been shown to exist for brittle materials:

$$\gamma_c = \gamma_s + \gamma_t + \gamma_i = \gamma_o + \frac{a_o D^* E}{2} \quad (25)$$

where γ_c = critical fracture energy (toughness).

γ_s = surface energy created during fracture.

γ_t = thermal energy during fracture.

γ_i = summation of all other energy contributions during fracture.

γ_o = fracture energy for a flat surface ($\gamma_o \sim 0$).

D^* = fractal dimensional increment of the fracture surface.

E = Young's modulus.

a_o = material structure constant.

The variables D^* , E , and γ_c are independently measurable; a_o can be calculated from these three variables without introducing any adjustable parameters. Eq. (25) can be considered representative of the toughness-tortuosity relation for glass, Ocala chert, intermetallics, ceramics and glass ceramics, i.e., the toughness increases as the tortuosity. Note that a crack propagating through a perfectly homogeneous material with thermal vibrations will not result in a smooth surface. Thus, we should not expect any fracture surface that involves fracture of primary bonds to be smooth if the fracture occurs above absolute zero! Thus, the value of γ_c in Eq. (25) can be thought of as the fracture toughness, inclusive of all contributing terms.

The significance of the scaling behavior observed on fracture surfaces is that fractography (Eq. 2), fracture mechanics (Eq. 1), and fractal geometry (Eq. 23) can be used to relate properties such as fracture toughness and elastic modulus with atomic or molecular level structural units. This knowledge can help describe the creation of the surface during bond rupture and crack propagation. The values of a_o are given in Table 1 for inorganic glasses, single crystals, and glass ceramics. The values of a_o for single crystals (1–10 Å) can be thought of as the size of stretched bond lengths. The values of a_o for glasses (10–20 Å) are consistent with the size of the free volume

Fig. 14 Schematic of multi-scale fracture processes. (a) Macroscopic fractography; (b) Molecular level fractal behavior; (c) atomic reconfigurations. The three scale levels are related through Eqs. 9, 23, and 25.

near the crack tip. The a_0 values for glass ceramics (20–60 Å) are consistent with the size of glass-crystal clusters. Thus, we can think of a_0 as related to the sizes of the initiation region at the tip of a crack that result in the propagation of the crack by self-replication.

Brittle fracture is most likely a series of quantized, bond reconfiguration events based on minimum energy related to the production of free volume at the crack tip (West *et al.*, 1999). A series of these reconfigurations along the crack front, due to thermal vibrations and lowest energy configurations, develop into a mirror-mist-hackle pattern. a_0 is an indirect measure of the space created at a point along the crack front. These enlarged spacings, in turn, annihilate and supplement other similar spaces either to subside or to percolate into large structures, respectively. D^* is a scaling factor for both the fracture energy and the geometry of the fracture surface created. At a critical point, the crack branches macroscopically. The angle and nature of the macroscopic branching depends on energy levels, geometric atomic structure, far field stress, and lowest energy pathways.

The relationship of the fracture process at different length scales is schematically shown in Fig. 14. On the macroscopic scale, continuum (fracture) mechanics can be used to identify many macroscopic quantities to be verified using fracture mechanics, fractography and fractal analysis. The crack size-to-mirror size ratio is a constant equal to the fractal dimensional increment, D^* . The c/r_1 ratio relates the initiation of crack propagation (Fig. 1) with the resulting fractographic features quantified by Eq. (2). On the molecular scale, molecular dynamics (MD) modeling describes the creation of the fracture surface and has been shown to compare well with the experimental observations by using the atomic force microscope (AFM) and by a comparison of the fractal dimensions (Tsai *et al.*, 1995). At the atomic level we can use quantum mechanics to describe fracture as a quantized ring

contraction dictated by minimum energy and creation of free volume. The geometry of the structure formed is the basis for the structure of the ensuing crack propagation (West *et al.*, 1999).

Thermal Analysis Techniques for Technical Ceramics and Glasses

Thermogravimetric Analysis

Introduction

Thermogravimetric analysis (TGA or TG) is a technique which continuously follows weight changes with temperature as well as weight changes at constant temperature. Accordingly, it can be used for various processes which involve weight gain e.g., oxidation of boride – carbide composites (Ren *et al.*, 2019) or weight loss e.g., decomposition of cerium nitrate (Storti *et al.*, 2019). For ceramic and glass science, the technique can be used to study the following: calcination, binder burn out, decomposition, pyrolysis, weight changes during crystallization or transformation, weight changes during oxidation or decomposition of ceramics, glasses and high temperature ceramics and composites. Thus, the technique can be used to aid the understanding of the kinetics and mechanisms of various physico-chemical processes involved in materials processing or materials degradation. Experiments can be carried out in complex gas environments as well as in neutral or inert gas environments.

Fig. 1 shows a typical setup for a thermogravimetric analyzer allowing experiments to be conducted under a nitrogen-carbon dioxide gas mixture. For this system, the balance mechanism is continually purged by nitrogen. However, a reaction gas (CO_2 in this instance) can be pumped over specimens which are held in a furnace chamber. Other designs are offered by the various TGA instrument manufacturers and suppliers, but all involve a specimen located in a furnace attached to a microbalance which is remote from the furnace. Computer controlled systems allow heating rates (in the range $0.1\text{--}500\text{K min}^{-1}$) up to temperatures of 2400°C . Multistep control facilities allow several different approaches to be adopted e.g., simple constant temperature ramp rate to a defined temperature, which can then be held to facilitate isothermal experiments, or multiple ramps and holds to facilitate examination of weight change events associated with different temperatures or heating rates. Weight change resolution typically depends on sample size, thus for a 5 g sample size Linseis indicate a $0.1\text{ }\mu\text{g}$ sensitivity. For a 25 g sample a $0.5\text{ }\mu\text{g}$ accuracy is indicated by them for their TGA PT 1600 system.

Examples of Thermogravimetric Analyzes for Ceramics and Glasses

The following paragraphs give examples of the use of TGA for the analysis of different processes of interest.

Fig. 2(a) shows the percentage weight changes associated with the decomposition of cerium III acetate hydrate to cerium IV oxide. In addition to measuring the weight change, Arii *et al.* (2002) passed the gases evolved through a mass spectrometer so that the exact decomposition mechanism could be ascertained. Gas analyzes can also be conducted using FT-IR spectroscopies and gas chromatography (Dollimore, 2003). The work of Arii *et al.* (2002) shows how different environments affect the decomposition rate over the temperature range covered and how the individual stages of decomposition can be clearly identified by using Sample Controlled TGA (SCTGA – see Rouquerol (2019) for a detailed description of the technique) where the rate of weight change is held constant (see Fig. 2(b)). Thus, the work of Arii *et al.* (2002) shows how versatile TGA analysis can be. The weight changes shown in Fig. 2 are expressed as a percentage of total weight of starting cerium acetate hydrate. This is adequate for the observation of each of the changes for each of the steps of the decomposition. However, this would not be adequate to truly assess the kinetics of the processes at each step because the decomposition rates will depend on surface area. Fig. 3 shows the weight gain of uncoated and coated silicon carbide when exposed to air at 1500°C . In this work by Bundschuh *et al.* (1995), the weight gain is expressed as weight change per unit area and thus the kinetics and mechanism of the oxidation processes can be truly ascertained. Thus, the uncoated silicon carbide undergoes diffusion controlled oxidation denoted by a parabolic weight change per unit area – time relationship. Bundschuh *et al.* (1995) used the TGA experiments to help select materials for use at 1500°C in air. Ren *et al.* (2019) used TGA similarly, to test mixtures of HfB_2 and SiC powders.

While the SCTG methods used by Arii *et al.* (2002) are useful in detecting the temperatures at which samples undergo weight change, this can also be done by the use of combined thermal analysis TGA/DSC or TGA/DTA. Fig. 4 shows combined TGA/DSC data for the thermal decomposition of $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ precursor used in the production of electrospun CaZrO_3 nanofibers. This work by Storti *et al.* (2019) shows that the calcium nitrate hydrate undergoes three stages of loss of physically absorbed water and water of crystallization at 51, 164 and 199°C and these events are associated with endothermic heat changes in the DSC curves. The endotherm at 557°C is said to be associated with the melting of anhydrous calcium nitrate and melting occurs prior to decomposition of the molten salt to CaO and NO_2 at 605°C . Similar analyzes can be conducted with 3D printing inks for ceramic components (Liu *et al.*, 2020). Fig. 5(a) shows the TGA/DTA curve for the decomposition of their ink. It is seen that at temperatures up to 700°C weight losses occur in stages associated with endothermic peaks. These are due to the evaporation of volatile organic constituents from the ink, although Liu *et al.* (2020) do not specifically indicate the decomposition products. They were however able to develop a temperature profile for sintering the 3D printed Li_2SiO_4 components with holds at 200 and 750°C to facilitate the total removal of the binder in the ink (see Fig. 5(b)). This then demonstrates how TGA can be used to design thermal programmes for binder or ink vehicle removal from processed green ceramics.

Differential Thermal Analysis and Differential Scanning Calorimetry

Introduction

Differential Thermal Analysis (DTA) and Differential Scanning Calorimetry (DSC) are experimental techniques which enable transitions and transformations to be analyzed in terms of the temperature they occur at and the specific energy associated with them (Wunderlich, 2001; Dollimore, 2003; Schick, 2016; Kett, 2019; Zheng *et al.*, 2019). Such transitions/transformations include dehydration, transformations in crystal structure, melting, the glass transition and crystallization of glasses. Indirect information such as specific heat capacity, glass viscosity for given temperatures and glass fragility can also be inferred from DSC/DTA data (see Zheng *et al.*, 2019). Perusal of relevant supplier websites shows a vast array of standard instruments are available with heating and cooling rates in the range $0.001\text{--}50\text{K s}^{-1}$ and maximum temperatures up to 2000°C . Typically samples of the order of 50 mg weight are used.

Wunderlich (2001), Dollimore (2003), Schick (2016) and Zheng *et al.* (2019) describe DSC/DTA in detail. Both systems involve a sample and an inert reference located in a single furnace or individual furnaces. DTA is also described as heat flux DSC. For DTA, heat is supplied to both reference and sample at the same rate within a single furnace (see Law and Zhou, 2017 for a suitable schematic). Both sample and reference materials absorb a level of heat energy Q . However, due to specific heat differences, the temperature increase caused by the absorption of Q will be different between the sample and reference and this temperature difference will linearly increase or decrease with increasing temperature depending on the relative specific heats of sample and reference. If then a thermally induced event arises, the heat input into the sample will change (e.g., it will increase for an exothermic event and decrease for an endothermic event). This additional heat input will result in greater temperature differences between sample and reference, generating a peak on a ΔT versus T trace. In many instances, ΔT is replaced by ΔV the voltage difference between the two thermocouples monitoring sample and reference temperatures (See Fig. 6). DSC, also referred to as power compensated DSC, involves analysis of the differential heat input required to maintain reference and sample at the same temperature (again see Law and Zhou, 2017 for a suitable schematic). The output signals are typically, W , $W\text{ g}^{-1}$, $W\text{ mol}^{-1}$, $W\text{ s}^{-1}$ (power output) among others. Fig. 5 gives an example.

Examples of DTA/DSC Analyzes for Ceramics and Glasses

Degradation, volatilization and melting

Figs. 5(a) and 6 show DSC and DTA curves for the decomposition of an organic printing ink (Liu *et al.*, 2020) and the dehydration, desulphurization and melting of constituents typically found in gas turbine deposits which attack environmental and thermal barrier coatings (Wiesner and Bansal, 2015). In the case of the printing ink its decomposition and volatilization of decomposition

Fig. 2 (a) TGA curves for decomposition of $\text{Ce}(\text{CH}_3\text{CO}_2)_3 \cdot 1.5\text{H}_2\text{O}$ at $0.5^\circ\text{C min}^{-1}$ in helium and $10^\circ\text{C min}^{-1}$ in vacuo. (b) Comparison of mass loss curves of $\text{Ce}(\text{CH}_3\text{CO}_2)_3 \cdot 1.5\text{H}_2\text{O}$, using LHTG (linear heating controlled TG) of $0.5^\circ\text{C min}^{-1}$ in helium and $10^\circ\text{C min}^{-1}$ in vacuo with SCTG (sample controlled TG) at $0.06^\circ\text{C min}^{-1}$ in helium. Reproduced from Ariei, T., Taguchi, T., Kishi, A., Ogawa, M., Sawada, Y., 2002. Thermal decomposition of cerium (III) acetate studied with sample-controlled thermogravimetric-mass spectrometry (SCTG—MS). *Journal of the European Ceramic Society* 22, 2283–2289.

products is evidenced by three significant endotherms arising between 300 and 600 °C (Liu *et al.*, 2020). Fig. 6 presents a DTA curve for the synthetic sand with a composition (in wt%) 34 SiO₂, 30 CaSO₄ · 2H₂O, 17 (SiO₂ + KAlSi₃O₈), 14 (Ca,Mg)(CO₃)₂ and 5 NaCl. Various endothermic events occur and can be associated with various changes to the synthetic sand ingredients. Thus, Wiesner and Bansal (2015) assign the endotherms as follows: 150 °C – dehydration of the hydrated calcium sulfate, 666 and 740 °C the decomposition of the carbonate to (Ca,Mg)O, 809 °C – the melting of the sodium chloride, 1175 °C – desulphurization of the calcium sulfate to CaO, further melting of the mixture resulting from the heating to above this temperature. This DTA data enabled Wiesner and Bansal (2015) to determine how molten CMAS glass deposits could form from a mixture of typical impurities ingested into a gas turbine. Pomeroy *et al.* (2011) also used DTA to investigate reactions between cordierite and an ash typical of that arising in diesel particulate filters. In this work, Pomeroy *et al.* (2011) were able to correlate an exothermic effect due to the combustion of carbon (simulating the carbon burnout cycle in a diesel particulate filter) and subsequent endothermic effects associated the decomposition of ash components (calcium sulfate, zinc sulfate). At temperatures above 900 °C, melting endotherms could be observed. Using combined findings from DTA, dilatometry and X-ray diffraction, Pomeroy *et al.* (2011) were able to clearly identify liquefaction events and how these events could be suppressed so that they occurred at higher temperatures in the presence of either Fe or Ce, which can be added to diesel fuel in combustion catalysts as ferrocene or cerium carboxylate.

Differential thermal analysis of glasses – Glass transition temperature

Without doubt the most comprehensive article on the differential thermal analysis of glasses is that by Zheng *et al.* (2019). However, the more general aspects of the topic are addressed in this present chapter. Fig. 7 shows a typical DTA curve for a relatively simple barium silicate glass. Four events can be discerned and are related by Rodrigues *et al.* (2018). These are: (1) the glass transition temperature indicated by an endothermic event at about 980K, (2) an exothermic event at about 1140K associated with major crystallization of the glass to a metastable monoclinic form, (3) a secondary exothermic event at about 1250K

Fig. 3 Weight gain per unit area of uncoated and MoSi₂-polysiloxane coated silicon carbide. Reproduced from Bundschuh, K., Schüze, M., Müller, C., Greil, P., Heider, W., 1995. Selection of materials for use at temperatures above 1500°C in oxidizing atmospheres. *Journal of the European Ceramic Society* 8, 2389–2391.

Fig. 4 DSC-TG curves of a Ca(NO₃)₂·4H₂O precursor used in the production of electrospun CaZrO₃ nanofibers. Reproduced from Storti, E., Himcinschi, C., Kortus, J., Aneziris, C.G., 2019. Synthesis and characterization of calcium zirconate nanofibers produced by electrospinning. *Journal of the European Ceramic Society* 39, 5338–5344.

associated with the transformation of the metastable monoclinic form to a stable orthorhombic form and (4) an endothermic event at about 1680K which is the system liquidus. [Rodrigues et al. \(2018\)](#) also indicate the onset of liquefaction as T_s the solidus temperature indicated by the inflexion at 1660K in [Fig. 7](#). With respect to the glass transition, it often appears as a slight deviation of

the baseline or a very small endotherm due the nature of the change in glass structure it represents. [Zheng et al. \(2019\)](#) show how more detailed analysis of T_g and temperatures related to it (T_g start, T_g end and ΔT_g – see [Fig. 7](#) in their publication), can be realised by using specific heat capacity data – T traces rather than raw DTA data. The specific heat capacity is determined using DSC data for the baseline, the reference and the sample (see [Shelby, 2005](#)). Netzsch for example have a software package to use the baseline, reference and sample data to determine C_p . [Eq. \(1\)](#) (see Hitachi website reference) gives the relevant equation where for a given temperature, C_{p_s} and C_{p_r} are the specific heat capacities of the sample and reference, H is the DSC output difference between sample and empty sample pan, h is the output difference between reference and empty sample pan and m_r and m_s are reference

Fig. 6 DTA curve (mV mg^{-1} vs. T) for a synthetic calcium magnesium aluminosilicate typical of a CMAS glass formed as deposits on barrier layers in gas turbines. Reproduced from Wiesner, V.L., Bansal, N.P., 2015. Mechanical and thermal properties of calcium–magnesium aluminosilicate (CMAS) glass. *Journal of the European Ceramic Society* 35, 2907–2914.

and sample weights. Shelby (2005) gives a similar method and equation for establishing C_p . Analysis of the variation is C_p with T is particularly useful. Eqs. (2) and (3) (see Schick, 2016) allow enthalpy (H) and entropy (S) to be calculated, and thus with care, a complete thermodynamic analysis of glasses over a suitable temperature range should be possible.

$$C_{p_s} = (H/h) \cdot (m_r/m_s) \cdot C_{p_r} \quad (1)$$

$$H = \int_0^T C_p \cdot dT \quad (2)$$

$$S = \int_0^T \frac{C_p}{T} \cdot dT \quad (3)$$

Interpolation of other important glass properties from DTA/DSC data

Viscosity data for a given temperature can be inferred from data obtained by differential thermal analysis using the Vogel-Fulcher-Tammann equation (see for example Wiesner and Bansal, 2015; Rodrigues *et al.*, 2018). This equation, given in Eq. (4), enables the calculation of viscosity (η) for a given temperature (T), if the constants A , B and T_0 can be evaluated from known viscosities and

Fig. 7 DTA curve for a barium silicate glass showing glass transition temperature, T_g , exothermic peaks between 1100 and 1300K are exotherms due to crystallization the inset shows endotherm onset and peak associated with solidus and liquidus temperatures T_s and T_L . Reproduced from Rodrigues, A.M., Cassar, D.R., Fokin, V.M., Zanolto, E.D., 2018. Crystal growth and viscous flow in barium disilicate glass. *Journal of Non-Crystalline Solids* 479, 55–61.

their corresponding specific temperatures. These specific temperatures are T_g , the dilatometric softening temperature (see Section “Phase Transformations”) T_D , the melting temperature, T_m , and their associated viscosities which are $10^{12.6}$, $10^{10.3}$ and 10^5 Pa s (see Bansal and Doremus, 1986). According to Zheng *et al.* (2019) and (2020) a more accurate method of estimating viscosity for a given temperature is the MYEGA (Mauro–Yue–Ellison–Gupta–Allan) equation (see Eq. 5). In the MYEGA equation, m , defined in Eq. (6), is the fragility index of the glass and η_∞ the viscosity at the high temperature limit, given as $10^{-2.93}$ Pa s by Zheng *et al.* (2019). The MYEGA equation relates to a viscosity at T_g of 10^{12} Pa s in contrast to the value of 10^{12} Pa s of Bansal and Doremus (1986). Because T_g values are dependent on heating rates the value of viscosity at T_g changes (see Shelby, 2005). As viscosity and temperature are related, DTA/DSC data can also be to interpolate the activation energy of viscous flow E_{vf} from the Arrhenius equation given in Eq. (7), where R is the gas constant, using calculated data for viscosity at specific temperatures. Calculation of E_{vf} from raw DTA/DSC data is also possible (see Moynihan *et al.*, 1996).

$$\ln_{10}(\eta)_{(T)} = A + \frac{B}{T - T_0} \quad (4)$$

$$\ln_{10}(\eta)_{(T)} = \ln_{10}(\eta_\infty) + (12 - \ln_{10}(\eta_\infty)) \cdot \frac{T_g}{T} \cdot \exp \left[\left(\frac{m}{\ln_{10}(\eta_\infty)} - 1 \right) \cdot \left(\frac{T_g}{T} - 1 \right) \right] \quad (5)$$

$$m = \frac{\delta \log_{10}(\eta)}{\delta \left(\frac{T_g}{T} \right)} \text{ for } T = T_g \quad (6)$$

$$\eta = A \cdot \exp \left[\frac{E_{vf}}{RT} \right] \quad (7)$$

In addition to the detailed information relating to viscosity and fragility which can be interpolated from DTA/DSC data, Zheng *et al.* (2019) also indicate how fictive temperature can also be inferred from it. The reportage of Shelby (2005) and the works of Moynihan *et al.* (1996) and Yue *et al.* (2002) act as a good starting point if the reader is interested further. A further glass parameter which may also be of use is glass stability. This is really the temperature range between T_g and the onset temperature for crystallization, say T_x . However, Zheng *et al.* (2019) catalog nine different glass stability parameter definitions which are expressed in terms of T_g , T_x , T_c and T_m . They sum up the available analysis of glass stability by indicating that T_x is often very difficult to discern at typical DTA/DSC heating rates ($5\text{--}20\text{K min}^{-1}$) and accordingly the ratio T_g/T_m is a very useful, but rough, indicator of glass stability and indeed glass forming ability. A final comment on other important information which can be gleaned from DTA/DSC data is the occurrence of more than one T_g value which is indicative of phase separated glasses (see Zheng *et al.*, 2019).

Crystallization of glasses – Crystal growth

As indicated above, crystallization occurs at a temperature T_c and is an exothermic process. Thus, the barium silicate system of Rodrigues *et al.* (2018) (Fig. 7) shows an exotherm at about 1140K which is associated with glass crystallization. The area of the exotherm, say A_0 reflects the total amount of heat released due to complete crystallization of the glass or the “crystallizable fraction” at a particular T_c in the case of a glass crystallizing to more than one phase at different T_c s. If, for a constant temperature, the progress of heat release can be followed with time, t , by assessing the area under the crystallization exotherm, A , the extent of crystallization, y , can be calculated (see Zheng *et al.*, 2019). This extent of reaction can then be substituted into the Johnson, Mehl,

Fig. 8 Typical Optimum nucleation plots as determined by the Marotta method. The plots shown are for a Ba-K-Mg-Si-Al-O glass with various hold times using original data (green 5 min hold; orange 15 min hold; blue 60 min hold; black 300 min hold).

Avrami, Yerofeev, and Kolmogorov (JMAK) equation (see Eq. 8). If repeated DSC experiments are conducted at different temperatures, it is possible to use the Arrhenius equation (see Eq. 9) to calculate the activation energy for the crystallization process (Shelby, 2005). Zheng *et al.* (2019) give a table of values of n associated with different mechanisms of crystallization. This methodology for following the kinetics of crystallization is clearly an isothermal method.

For isochronal kinetic analysis, Shelby (2005) gives the 1956 Kissinger equation correlating heating rate, ϕ and crystallization temperature, T_p , with an activation energy for crystallization, E . This equation was modified by Matusita and Sakka (1980) due to the fact that the Kissinger equation related solely to surface crystallization events. Eq. (10) gives the modified Kissinger equation. In Eq. (10), $m = n = 1$ for surface crystallization Matusita and Sakka (1980) or $m = n = 3$ as used by Ramesh *et al.* (1998) for a glass undergoing crystallization from a fixed number of nuclei formed within the bulk of the glass. A more detailed derivation of the method and a wider range of m and n values associated with specific crystallization mechanisms is given by Matusita and Sakka (1981).

$$\ln(-\ln(1 - y)) = \ln(k) + n \cdot \ln(t) \quad (8)$$

$$\ln(k) = \ln(A) - E/RT \quad (9)$$

$$\ln\left(\frac{\alpha^n}{T_p}\right) = \ln(k) - \frac{m \cdot E}{RT_p} \quad (10)$$

Crystallization of glasses – Nucleation

As indicated above, the crystallization of glasses can occur within the bulk of a glass or at its surface, depending on whether preferred nucleation is homogeneous (bulk) or heterogeneous (surface). DSC/DTA experiments using different particle sizes enable which nucleation process predominates. Fernandes *et al.* (2019) shows a series of DSC curves for different particle size fractions of a glass. The data shows an increase in the value of the crystallization peak temperature and analysis of the glass crystallization shows that it surface nucleates and the nuclei grow inwards yielding crystals which grow from the surface into the glass. In contrast, for a bulk nucleating Y-Si-Al-O-N glass Ramesh *et al.* (1998) observed T_{p1} (first crystallization peak temperatures) of 1135, 1136 and 1136°C for glass particle sizes of <53, 53–106 and >106 μm . The differences for surface and bulk nucleation can be simply related to the fact that finer particle sizes have greater specific area and so for the same weight of glass powder, finer particle sizes will undergo greater rates of crystallization at lower temperatures. Large particles will have far less specific surface area and thus crystallization will need more thermal energy (higher temperature).

For homogeneous nucleation, it is possible to determine an optimum nucleation temperature at which the nucleation rate is a maximum. Marotta *et al.* (1985) derived a suitable equation given by Eq. (11), where I is the nucleation rate constant, n is a constant associated with nucleation mechanism, E is the activation energy for nucleation, R the gas constant, T_p° is the crystallization peak temperature for a glass and T_p the crystallization peak temperature for samples of the same glass having undergone nucleation holds at a temperature T_n . A plot of $(1/T_p) - (1/T_p^\circ)$ against T_n gives a bell shaped curve whose maximum is at the temperature of the maximum rate or, the optimum nucleation temperature (see Fig. 8). Zheng *et al.* (2019) report that plots of crystallization temperature against nucleation hold temperature, or the peak width at half maximum for the crystallization exotherm can be used to identify the optimum nucleation temperature. For the latter, as the peak width at half maximum is indicative of time for complete crystallization, for a constant crystal growth rate the smaller the width, the higher the nucleation rate. With respect to the actual value of the optimum nucleation temperature, Rafferty *et al.* (2000) note that if its value is close to T_g then the glass is highly likely to be phase separated.

$$\ln(I) = \frac{n \cdot E_c}{R} \cdot \left(\frac{1}{T_p} - \frac{1}{T_p^\circ} \right) + C \quad (11)$$

Fig. 9 Expanded DTA curve showing transformations of yttrium disilicate arising during the thermal treatment of a Y-Si-Al-O-N glass. Redrawn from Pomeroy, M.J., Hampshire, S., 2008. Controlled crystallisation of a Y-Si-Al-O-N glass typical of grain boundary glasses formed in silicon nitride-based ceramics. *Journal of the Ceramic Society of Japan* 116, 722–726.

DTA/DSC analysis of phase transformations

Many ceramic phase undergo transformations above certain temperatures. The work of [Rodrigues *et al.* \(2018\)](#) shows a DSC peak just above 1200K which is attributed to the transformation of the metastable monoclinic form of BaSi_2O_5 to a more stable orthorhombic form. No investigation of the mechanism of transformation is reported. However, it is important to indicate that as well as a solid state transformation occurring by atomic rearrangement, a solution - precipitation mechanism could also pertain. Such a transformation has been observed by [Pomeroy and Ramesh \(1993\)](#) where the β -polymorph of $\text{Y}_2\text{Si}_2\text{O}_7$ dissolves in a viscous liquid during the oxidation of β -sialons and re-precipitates as the γ -polymorph. This observation was due to X-ray analysis only. However, [Pomeroy and Hampshire \(2008\)](#) also report X-ray diffraction analysis of the devitrification of a Y-Si-Al-O-N glass to different polymorphs of $\text{Y}_2\text{Si}_2\text{O}_7$. They were able to correlate the temperatures at which the γ -form transformed to the α -form then to the β -form and then the δ -polymorph after a nucleation hold. It then became apparent that these transformations could be mapped onto an expanded DTA trace and discontinuities in the trace correlated with the formation of each polymorph and the crystallization of silicon oxynitride (see [Fig. 9](#)). Thus, [Pomeroy and Hampshire \(2008\)](#) were able to interpret the development of intergranular phases formed in silicon nitride densified with yttria and alumina.

Not only can phase transformations in glasses be followed using differential thermal analysis, but phase transformations in ceramics can also be followed. One example is the analysis of the phase transformations of $\text{La}_2\text{Mo}_2\text{O}_9$ and substituted variants from a monoclinic to cubic form on heating ([Ali *et al.*, \(2009\)](#)). This work also shows the importance of following a cooling curve as well as a heating curve. In their work, [Ali *et al.* \(2009\)](#) were able to clearly show that the reverse transformation involved the transformation to a metastable γ -form prior to that fully converting to the monoclinic form on further cooling. This shows the importance of following cooling curves, particularly since when some La was replaced by Sr, no intermediate γ -form arose.

Advanced Differential Thermal Analysis Techniques

Flash DSC and modulated DSC are modified DSC techniques, designed to yield additional and more detailed observations. Flash DSC is well described by [Schick \(2016\)](#), [Schawe and Hess \(2019\)](#) and [Zheng *et al.* \(2019\)](#). Exceedingly small samples, a few nanograms for the work of [Schawe and Hess \(2019\)](#), are heated or cooled at rates between 5K s^{-1} and $30,000\text{K s}^{-1}$ on an adiabatic heating chip. The incredible variation in heating and cooling rates facilitate more accurate assessments of glass transition temperatures as well as an ability to monitor the kinetics of this secondary transition (see [Schawe and Hess, 2019](#)). In addition to this level of detailed analysis, glass viscosity – temperature curves could be interpolated for the glass in question as could thermal relaxation times. [Zheng *et al.* \(2019\)](#) also explain how flash DSC can be used to interpolate fictive temperature and glass fragility index.

Modulated DSC involves a sinusoidal temperature modulation added to the simple linear heating rate such that the temperature cycles about a temperature step as it increases with time. According to [Dollimore \(2003\)](#) and [Kett \(2019\)](#) a sinusoidal, square or sawtooth cycle is superimposed upon a linear heating rate curve. Thus, detailed temperature cycling about each temperature is realised during heating. [Ketts \(2019\)](#) clearly indicates how the modulated approach separates out transitions related solely to heat capacity, whereas traditional DSC probes overlapping kinetic events. As clearly shown by data presented by [Ketts \(2019\)](#) the secondary transition, T_g , can clearly be identified by modulated DSC. [Zheng *et al.* \(2019\)](#) also discuss the benefits of modulated DSC for the study of glass systems.

Fig. 10 Dilatometric shrinkage (Y) and shrinkage rate (dY/dT) curves for nanometric hematite at heating rates of 5, 10, 15 and $20^{\circ}\text{C min}^{-1}$. Dilatometry

Introduction

Dilatometry is a relatively simple technique where a specimen is heated in a furnace and changes in length measured by an extensometer at the end of a pushrod linking the sample and the extensometer. Relating these changes in length to original length allows thermal strain to be determined over a temperature range and this enables coefficient of thermal expansion (CTE) to be determined. Typically, measurement accuracies of 0.05 nm and better are achievable and this is over a specimen of length up to 25 mm. This allows strains to be determined with accuracies of 5×10^{-9} . Current instruments (see list of supplier websites in the reference list) allow total length deflections of up to 5 mm to be followed i.e., total strains of the order of 20% for a 25 mm long specimen. Length deflections over temperature ranges from -180 to 2800°C can be conducted. More generally, the range ambient to 1600°C suffices. Sample environments can be vacuum, inert gases, nitrogen, air and oxygen. Only in graphite furnaces, used for very high temperatures, can reducing gases be employed. Typical accuracies for thermal expansion coefficients are $0.01 \times 10^{-6}\text{K}^{-1}$. The resolution of dilatometric change can be improved by using temperature modulated systems.

Dilatometers using optical sensors are now available. These dilatometers use either high resolution camera images to measure the length of a sample and reference and hence sample dimensional change (see Linseis website), or they use a shadowed light method to obtain accurate absolute length measurements of a sample (see TA Instruments website). In the case of the latter system, because it uses absolute measurement, tedious calibrations are not necessary. Depending on the system, accuracies in measurements are of the order of $0.05\text{--}1\text{ }\mu\text{m}$ and samples ranging from thin films to relatively large cylinders/trapezoids, can be measured. Experiments can be carried out in a range of environments including reducing environments.

As volume, and therefore length, changes occur when ceramic powders are sintered into dense bodies, the effect of temperature on sintering behavior can be observed as can sintering rates as a function of temperature. Sintering curves and rates can then be used to improve or optimize sintering regimes in the laboratory or in Industry. In addition to CTE data, values for glass transition temperature (T_g) and glass softening temperature (T_D) can be obtained with glasses due to the marked volume expansion which occurs at T_g and the inability of a glass to withstand a very small applied force ($\sim 1\text{ N}$) necessary to maintain contact between the sample and measuring sensor. The inability to withstand this force results in flow and a rapid contraction of the glass sample length at T_D . Another use of dilatometry is the determination of temperatures at which solid state transformations occur and the strains associated with them.

Examples of Dilatometric Analyses for Ceramics and Glasses

Analysis of sintering

Fig. 10 shows dilatometric shrinkage curves (Y or $(\Delta L/L_0)$ versus T curves) associated with the sintering of nano-sized haemetite using different heating rates in a conventional dilatometer (Togashi *et al.*, 2020). It is seen that little shrinkage occurs until about 700°C . At higher temperatures, shrinkages increase until they are complete at about 1140°C . From the $Y - T$ curves, it is difficult to identify a major effect of heating rate on shrinkage. However, Togashi *et al.* (2020) also include shrinkage rate (dY/dT versus T) curves and these allow a more informed understanding which shows that the lowest heating rate gives rise to a greater shrinkage rate at a lower temperature (just below 1050°C). Using data such as this helps selection of sintering temperatures and hold times which help to minimize grain growth and develop master sintering curves as per the work of Du (2020) for example. Pillai *et al* (2004) used sintering rate curves to identify how the use of different additives could optimize the additive type (see Fig. 11). The

Fig. 11 Dilatometric shrinkage rate – T curves for alumina – silicon carbide nanocomposite showing the effect of different additives. Reproduced from Pillai, S.K.C., Baron, B., Pomeroy, M.J., Hampshire, S., 2004. Effect of oxide dopants on densification, microstructure and mechanical properties of alumina-silicon carbide nanocomposite ceramics prepared by pressureless sintering. *Journal of the European Ceramic Society* 24, 3317–3326.

figure shows that the best additive system to effect the densification of an alumina matrix – SiC nanoparticle nanocomposite is yttrium oxide. In addition, the sintering could be done at much lower temperatures than for the other compositions employed in the work of Pillai *et al.* (2004). A further example of the use of dilatometry to understand and optimize sintering is to use it for rate controlled sintering (RCS). Maksimov *et al.* (2018) show how pre-sintering ytterbia doped leutetia ceramics at a controlled sintering rate can limit grain growth, thus advancing transparency. Maksimov *et al.* (2018) pre-sintered samples to 97% relative density using sintering rates controlled by the dilatometer output. Following HIPping to full density, the average grain sizes of the RCS materials were much finer than those where pre-sintering had been carried out using a conventional ramp and hold sintering régime. These finer grain sizes resulted in increased optical transmittance.

Phase transformation

Tiefenbach *et al.* (2002) used dilatometry to study the effect of grain size on the tetragonal to monoclinic phase transformation which zirconia undergoes as it is heated to temperatures above 250°C. The dilatometry data these workers gathered is given in Fig. 12 and shows how the transformation temperature increases with grain size.

Barium titanate undergoes transformation from a ferroelectric perovskite phase to cubic non-polar modification at 120°C. He (2004) has shown this using dilatometry and careful experimentation showed that there was a negative CTE just above the Curie temperature as was expected. Between 0 and 50°C the observed CTE value was around $6.1 \times 10^{-6} \text{K}^{-1}$ compared to $11.3 \times 10^{-6} \text{K}^{-1}$ between 150 and 200°C. The works of Tiefenbach *et al.* (2002) and He (2004) exemplify the ability of dilatometry to identify the temperatures of phase transformations and changes in CTE values associated with them.

Measurement of coefficient of thermal expansion, glass transition temperature and dilatometric softening point of glasses

Fig. 13 shows dilatometry curves for MgO-SrO-SiO₂ glasses doped with Eu₂O₃ or Eu₂O₃-Dy₂O₃ obtained by Fernández-Rodríguez *et al.* (2021). The slopes of these curves represent the CTEs of the glasses, and these are seen to increase when the dopants are

Processing and luminescence of Eu/Dy-doped Sr₂MgSi₂O₇ glass-ceramics useful dilatometry and DTA data. *Journal of the European Ceramic Society* 41, 811–822.

Fig. 14 Schematic dilatometry curves for annealed and non-annealed glass samples (arrow marks start of sub- T_g relaxation for the non-annealed glass sample).

added. Thus, the addition of the dopants increase the CTE, most probably due to greater levels of disruption of the glass network. CTE data has been correlated with the cation field strength of glass modifiers (Pomeroy *et al.*, 2005). When a glass is heated through its glass transition temperature, the structural units are free to move and the volume of the glass increases at a faster rate than at temperatures below the glass transition temperature. This is reflected in Fig. 13 where a relative length increase over a small temperature difference (about 20°C) is observed. The point of inflection corresponding to the glass transition temperature (T_g) is marked on Fig. 13. The glass continues to expand at this rate until the dilatometric softening temperature T_D is reached. At this point, the glass begins to flow under the small load applied by the pushrod. Using correlations given by Wiesner and Bansal (2015), it is possible to use the T_g and T_D data obtained by dilatometry to develop a viscosity temperature curve using the Vogel–Fulcher–Tammann equation (Eq. 4). These authors assign viscosity values of $10^{12.6}$ and $10^{10.3}$ Pa s to T_g and T_D respectively.

When carrying out dilatometry of glasses it is also possible to determine if the glass sample is fully annealed. Fig. 14 shows schematic dilatometry curves for two samples of a rapidly cooled glass. One sample is fully annealed whilst the other is unannealed. It is seen that there is a temperature at which the two curves separate indicated by the arrow. Above this temperature the unannealed glass undergoes little strain until a temperature close to T_g is approached. This effect is discussed for a variety of glasses by Kaur *et al.* (2018). These authors note how extended annealing increase T_g values and densities. These changes are attributed to increased cross-linking of glasses during annealing. Thus, for borate glasses, annealing increased the number of tetrahedral linkages and for lead silicate glasses, a larger proportion of Q^3 species were evident after annealing.

Sometimes, perhaps reasonably often, discrepancies arise between T_g values measured by dilatometry and those measured by DSC or DTA. These discrepancies are most likely to arise from (1) the small load applied by the dilatometer inducing a volumetric and therefore linear dimensional change at lower temperatures than might be expected from DSC or DTA, and (2) poorly annealed

glasses undergoing greater amounts of pre- T_g relaxation in dilatometer systems due to the slower heating rates used (see [Shelby, 2005](#); [Naji et al., 2013](#)).

One final comment on dilatometry is the need to investigate the modes for standard modes of dilatometer usage. Perusal of the necessary US, European and International standards is advisable when measuring CTE values.

High-Temperature Characterization of Glasses and Melts

Sohei Sukenaga and Hiroyuki Shibata, Tohoku University, Sendai, Japan

Introduction

The physical properties of oxide glasses and their melts at elevated temperatures are important for understanding high-temperature phenomena in the glass-melting process. High-quality flat glass was manufactured very efficiently using the float process in a bath of molten tin, a process invented by Pilkington and Bickerstaffe in 1953 (Hynd, 1984). This process enables the production of flat glass of the highest quality at thicknesses of 2–25 mm. Fig. 1 shows a schematic illustration of the float process (Achintha, 2016). In a glass-melting furnace, molten glass is formed by melting a mixture of several types of raw materials (e.g., SiO_2 , Na_2CO_3 , CaCO_3). To produce high-quality glass, it is essential to enhance the homogeneity of the glass components and remove bubbles from the melting furnace as much as possible because the inhomogeneity of glass (components and bubbles) has a negative influence on the appearance and properties of the glass materials. To consider the process of bubble removal from molten glass, the estimated velocity v_B of the rise of a bubble is expressed using Eq. (1) (Jucha *et al.*, 1982; Cable, 1984):

$$v_B = \frac{\rho g \chi^2}{12\eta} \quad (1)$$

where ρ and η are the density and viscosity of the molten oxide, respectively, and χ is the diameter of the bubble. Viscosity and density are essential in the elimination process of bubbles. In most molten glass, complete removal of bubbles takes time because glass-forming melts are highly viscous (e.g., $10^{0.5}$ – $10^{1.5}$ Pa s) even at temperatures higher than those of their liquidus (Bansal and Doremus, 1986).

Considering the float bath used in this process to control the thickness of the flat glass in the float process, understanding and estimating how the shape of the molten glass is manifested on the molten tin bath is necessary. Fig. 2 illustrates the force balance at the interface between the molten glass and the tin melt. Assuming equilibrium conditions, the thickness of molten glass (T_e) is given by Eqs. (2) and (3) (Hynd, 1984):

Fig. 1 Schematic of the production of float glass. Reproduced from Achintha, M., 2016. Chapter 5 – Sustainability of glass in construction. In: Khatib, J. (Ed.), Sustainability of Construction Materials, second ed. Cambridge: Woodhead Publishing, pp. 79–104.

Fig. 2 Schematic of the equilibrium thickness where $S_{ga} = (\gamma_{ga})$: surface tension of molten glass (N m^{-1}), $S_{gt} = (\gamma_{gt})$: interfacial tension between molten glass and tin melt (N m^{-1}), and $S_{ta} = (\gamma_{ta})$: the surface tension of molten tin. Reproduced from Hynd, W.C., 1984. Flat glass manufacturing processes. In: Uhlmann, D.R., Kreidl, N.J. (Eds.), Glass: Science and Technology, Volume 2, Processing I. pp. 46–106.

$$T_e = \sqrt{(\gamma_{ga} + \gamma_{gt} - \gamma_{ta})/A} \quad (2)$$

$$A = g \left(\frac{\rho_g}{2} \right) \left(1 - \frac{\rho_g}{\rho_t} \right) \quad (3)$$

where γ_{ga} is the surface tension of the molten glass (N m^{-1}), γ_{gt} is the interfacial tension between the molten glass and tin melt (N m^{-1}), γ_{ta} is the surface tension of molten tin, ρ_g is the density of molten glass (kg m^{-3}), and ρ_t is the density of molten tin (kg m^{-3}). Although the float process is rarely operated in equilibrium mode, it is still important for engineers to understand the fundamentals of this phenomenon, for which the density and surface tension of molten glass are important physical properties.

Recently, vitrification has been used for the long-term storage of nuclear waste. In this process, hazardous waste is mixed with glass-forming components (e.g., borosilicate glass). The mixture is then melted in furnaces using joule heating. To control the melting process, the physical properties (e.g., viscosity, electrical conductivity, thermal conductivity) of their melts are very important. For example, the viscosity of molten glass was controlled within the range of 2–11 Pa s in a joule-heated waste melter (Bickford *et al.*, 1990). In other high-temperature industries, metallurgical processes use molten oxides as refining agents for metals, and in this process, the properties of molten oxides (i.e., slag) play important roles in improving the product quality and process efficiency (Mills *et al.*, 2014). In addition, molten oxides are found in nature as magma, and their properties are strongly related to the evolution and dynamics of the earth's surface and crust (Mysen and Richet, 2019). Techniques to measure the physical properties of oxide melts have been developed in the fields of material science, earth science, and fundamental physics over a long period of time. In this chapter, we explain the measurement techniques and the conventional procedure used to interpret the most fundamental properties, that is, viscosity, density, and surface tension, obtained at temperatures above those of their liquidus.

Viscosity

For a shear force applied to a melt, viscosity (η) is defined as a measure of the ratio of the force to the flow rate. Because the viscosity of molten oxides is highly sensitive to the melting temperature, the state of melts (i.e., characteristic temperature) is commonly characterized using the melt viscosity, for example, the glass transition temperature ($\eta \approx 10^{12}$ Pa s), softening point ($\eta \approx 10^{6.6}$ Pa s), and working point ($\eta \approx 10^3$ Pa s). These characteristic temperatures are essential knowledge when shaping and annealing glass products in glass industries. In glass-melting, η is normally controlled in the range of $10^{0.5}$ – $10^{1.5}$ Pa s (Martlew, 2005) because the viscosity directly influences several high-temperature phenomena, such as the flow behavior and reaction rate of molten oxides with refractory materials. In the present section, we particularly focus on viscosity measurement techniques at temperatures above those of their liquidus, where η is generally lower than 10^3 Pa s. The viscosity for lower temperature regions ($\eta > 10^3$ Pa s) has been discussed and summarized in books and papers (see further reading section). In addition, the conventional understanding of the characterizing procedures for viscosity data is shown.

Measurement Methods

To measure viscosity, an external force is applied to the melt. The measurements are then performed under dynamic conditions. Measurement techniques vary depending on the viscosity range, as the viscosity varies widely depending on the temperature and chemical composition. Here, we focus on the measurement technique, particularly for the lower viscosity range ($< 10^3$ Pa s) in which a conventional rotating cylinder method provides a reliable value. A sphere pulling method is also commonly used for this viscosity range (Shartsis and Spinner, 1951; Suzuki *et al.*, 2015). Recently, some container-less methods (levitation techniques) have been applied to measure the viscosity of oxide liquids. The rotating cylinder method and recent levitation techniques are explained in detail in the following sections.

Rotating cylinder method

Fig. 3 shows the principle of the rotating cylinder method. Two concentric cylinders (i.e., inner and outer cylinders) are prepared. The torque exerted on the inner cylinder is measured using a torque meter when one of the cylinders is rotated. Ideally, the viscosity should be as expressed by Eq. (4) (Mills, 1995):

$$\eta = \frac{M_t}{8\pi^2 v h} \left(\frac{1}{r_1^2} - \frac{1}{r_2^2} \right) \quad (4)$$

where M_t is the detected torque, v is the number of rotations per second, h and r_1 are the height and radius of the inner cylinder, respectively, and r_2 is the radius of the outer cylinder. Since Eq. (4) assumes infinitely long cylinders, the viscometer is commonly calibrated at room and elevated temperatures using reference materials (e.g., silicone oil). To calibrate the viscometer at elevated temperatures, some high-temperature reference materials have been produced by the National Institute of Standards and Technology (NIST), e.g., soda-lime silica (NIST standard reference material 710) and high boron glass (NIST standard reference material 717a). Similarly, the SRM2 standard-viscosity material (lithium aluminosilicate glass) has been used in the metallurgical research field (Mills, 1995). In general, the rotating cylinder method is applicable for a viscosity range of 10^{-1} – 10^8 Pa s (Martlew, 2005). However, the range strongly depends on the detection range of the torque meter as well as the dimensions of the inner and outer cylinders.

Fig. 3 Schematic of a typical setup of the inner and outer cylinders in the rotating cylinder method.

Fig. 4 Schematic of an experimental setup of viscosity measurement using aerodynamic levitation. Reproduced from Kondo, T., Muta, H., Kurosaki, K., *et al.*, 2019. Density and viscosity of liquid ZrO₂ measured by aerodynamic levitation technique. *Heliyon* 5, e20249.

Takeda *et al.* succeeded in applying this method to the lower viscosity range ($< 10^{-2}$ Pa s) by optimizing the shape of the inner and outer cylinders (Takeda *et al.*, 2020). In addition, the rotating cylinder method is advantageous for altering the shear rate in the viscosity measurement. As such, the method can be applied to both Newtonian and non-Newtonian fluids. In the field of metallurgy, the apparent viscosity during melt crystallization has been evaluated for industrial and scientific purposes (Harada *et al.*, 2018; Liu *et al.*, 2019; Saito *et al.*, 2009; Wright *et al.*, 2000). Another important aspect of performing reliable measurements is the selection of the appropriate contact material. The rotating cylinder method requires the contact materials to be sufficiently rigid to avoid deformation at elevated temperatures. Commonly, Pt–Rh alloys are used in oxidizing or intermediate conditions (e.g., Kim and Park, 2014; Saito *et al.*, 2003), and Mo, W, and graphite are used in reducing atmospheres (e.g., Chen *et al.*, 2014; Sukenaga *et al.*, 2020). Au is an appropriate contact material for TeO₂ containing system (Tokunaga *et al.*, 2010; Wilding *et al.*, 2016).

Levitation method

Although conventional container-based techniques (e.g., rotating cylinder method) are well-established and provide a reliable value of viscosity, the maximum temperature that can be examined is limited by the melting point of the contact materials. Levitation techniques are advantageous for measuring the viscosity of refractory melts at ultra-high temperatures (> 2200 K) without the need of a container that may be reactive to the sample melt. Sample levitations are commonly obtained using “aerodynamic” or “electrostatic” levitation with a CO₂ laser heating system (Langstaff *et al.*, 2013). Because viscosity is related to the damping behavior of an oscillating droplet, acoustic excitation must be applied to provide surface oscillation to the levitated melt using a frequency generator. Fig. 4 depicts the typical setup for viscosity measurement using aerodynamic levitation. The damping constant of the resonant oscillations of the droplet, Γ , is given by Eq. (5):

$$\Gamma = \frac{5}{\rho R^2} \eta, \quad (5)$$

where R is the radius of the oscillating sphere (sample melt), ρ is the density, and η is the viscosity. In practice, the sample droplet is acoustically excited. When the excitation is removed, the decay of the oscillation amplitude is obtained to determine Γ . The detailed procedure is explained in the literature (Langstaff *et al.*, 2013; Nakamura *et al.*, 2019). Levitation viscometry has been used for systems with high melting points ($> 1900\text{K}$), where the viscosities of refractory melts, such as Al_2O_3 (Langstaff *et al.*, 2013), ZrO_2 (Kondo *et al.*, 2019), $\text{CaO-Al}_2\text{O}_3$ (Nakamura *et al.*, 2019), and $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3$ (Siafakas *et al.*, 2018a,b) have been reported. This method works well for samples with low viscosities ($< 0.1\text{ Pa s}$) and negligible sample evaporation rates.

Fig. 5 summarizes the viscosity measurement techniques with the viscosity range. By combining the levitation method with conventional container-based techniques, the applicable scope of viscosity measurement is expanding. Detailed information on other viscosity measurement techniques is presented in references (see further reading section).

Characterization Procedure of Viscosity Data

The viscosity of liquids exponentially increases with decreasing temperature. Typically, the logarithmic viscosity ($\log \eta$) is used to plot data against the reciprocal temperature. Fig. 6 depicts an example of the temperature dependence of the viscosity of a sodium silicate melt (Neuville, 2006). The liquidus temperature (T_l) and glass transition temperature (T_g) are important specific temperatures for categorizing the melt depending on their temperature range: liquid at T above their T_l , supercooled liquid ($T_g < T < T_l$), and glass ($T < T_g$). For viscosity data over a wide temperature range (i.e., from temperatures above that of the liquidus to temperatures close to the glass transition), the viscosity increases non-linearly with decreasing temperature (see Fig. 6(a)). Empirically, the Vogel–Fulcher–Tamann (VFT) equation, expressed in Eq. (6), reproduces the non-linear relationship using three fitting parameters: A_{VFT} , B_{VFT} , and C_{VFT} (Fulcher, 1925).

$$\log \eta = A_{\text{VFT}} + \frac{B_{\text{VFT}}}{T - C_{\text{VFT}}} \quad (6)$$

A_{VFT} , B_{VFT} , and C_{VFT} are the pre-exponential factor, pseudo-activation energy, and VFT-temperature, respectively (e.g., Giordano *et al.*, 2008). Although the physical interpretation of these fitting parameters (A_{VFT} , B_{VFT} , and C_{VFT}) remains to be understood, this equation is useful and commonly applied to express the temperature dependency of the viscosity over a wide temperature range. To understand the physical insight into the temperature dependence over a wide temperature range, several viscosity models have

Fig. 5 Typical viscosity measurement techniques are shown with their conventional applicable viscosity range. The applicable viscosity ranges are drawn according to the corresponding reference papers: beam bending, penetration, rotating cylinder, parallel plate, sphere pulling, oscillating crucible, and oscillation droplet. been developed (Avramov and Milchev, 1988; Ikeda and Aniya, 2013; Mauro *et al.*, 2009). As a successful example, Adam and Gibbs proposed a model relating the relaxation time (i.e., viscosity) to the configurational entropy ($S_c(T)$) using Eqs. (7) and (8) (Adam and Gibbs, 1965):

$$\log_{10} \eta = A_e + \frac{B_e}{TS_c(T)} \quad (7)$$

$$S_c(T) = S_c(T_g) + \int_{T_g}^T \frac{C_p^{\text{conf}}}{T} dT \quad (8)$$

where A_e and B_e are constants for each sample composition and C_p^{conf} is the configurational heat capacity. C_p^{conf} is a measurable parameter. When C_p^{conf} is known for the target composition, the viscosity curve is fitted using three parameters: A_e , B_e , and $S_c(T_g)$. The configurational entropy of the glass, $S_c(T_g)$, is a meaningful parameter for understanding the glass structure (Neuville, 2006; Richet, 1984; Toplis *et al.*, 1997). Meanwhile, the mixing state of the chemically distinguishable units, bond distances, and bond angles are related to $S_c(T_g)$.

In the narrow temperature range at temperatures above their liquidus, $\log \eta$ linearly increases with decreasing temperature (see Fig. 6(b)). When $\log \eta$ is plotted against the reciprocal absolute temperature (T^{-1}), the slope can be related to the activation energy of viscous flow:

$$\log \eta = A_a + \frac{E_\eta}{2.303 \cdot R_g \cdot T} \quad (9)$$

where A_a is a composition-dependent constant, E_η is the activation energy of viscous flow, and R_g is the gas constant. However, the physical meaning of the activation energy is still under discussion. Toplis *et al.* (1997) analyzed the viscosity based on the Adam–Gibbs model and proposed that the viscosity in this region reflects the average bond strength of the melt. Overall, the viscosity at temperatures above their liquidus decreases through the depolymerization of silicate anions (i.e., an increase in the non-framework cations, such as alkali or alkaline-earth cations, see Fig. 6(b)). The viscosity of molten oxides has been measured for a wide range of compositions. These data are summarized in books and databases (see further reading section).

Density

In industries that commonly use high temperatures (e.g., glass making and metallurgical extractions), the melt density is an important property that is related to the phase separation process in multi-phase mixtures (liquid/liquid, liquid/solid, or liquid/gas). This value is also essential in simulating the density-driven liquid flow and thermal expansion of molten oxide in a melting furnace. In addition to its industrial importance, melt density is a good indicator of melt structure because the molar volume and atomic packing density are derived from melt density. It is well known that network forming cations (e.g., Si⁴⁺) prefer to exist as corner-sharing tetrahedra, which are commonly linked to a decrease in the atomic packing density (Kohara *et al.*, 2010; Zachariasen, 1932). Meanwhile, network modifiers (e.g., Ca²⁺, Na⁺) form the breakage region of the network structure, which normally has a higher packing density than the network structure because of the edge- or face-sharing local structure of modifier cations (Greaves, 1985; Warren, 1941). The density of oxide melts (and their glasses) is meaningful for understanding the structural roles

Fig. 7 Schematic of the principle of the double-bob Archimedean method, where θ represents the contact angle between the wire and the melt. The white arrows in the figure indicate the force exerted on the wire due to the surface tension of the melt.

of each oxide component in the melts as well as improving industrial processes. The density was measured using some well-established techniques that require contact materials. Recently, a container-less technique has been developed, which will expand the possibility of density measurements for more extreme conditions. In this section, the advantages and limitations of each measurement method are shown. A typical procedure for analyzing density data is also explained.

Measurement Methods

The liquid density, ρ , is simply defined as the ratio of the mass to the volume ($\rho = M/V$). Indeed, for a liquid at room temperature, it is not so difficult to measure its volume and mass. However, this is not the case for a high-temperature melt because the sample liquid needs to be melted using a furnace, where there are some limitations and difficulties in observing the volume and mass of the samples. Conventionally, the density of molten oxides has been evaluated using the Archimedean, sessile drop, or maximum bubble pressure (MBP) methods. Recently, levitation techniques (e.g., aerodynamic levitation, electrostatic levitation) have been applied to measure density. Here, the principle, characteristics, and limitations of the Archimedean, sessile drop, and levitation methods are discussed. The MBP method is used to measure the surface tension; however, the method allows us to estimate the density of the sample as a by-product. The details of the MBP method are explained in the section entitled “Surface Tension”.

Archimedean method

When an object is immersed in a liquid, the object assumes a buoyancy, which indicates the weight of the displaced liquid. This principle is known as the Archimedean method and is one of the best-established techniques to determine melt density. The concept of the Archimedean method is shown in Fig. 7.

The Archimedean method determines the melt density, ρ , by measuring the mass of a bob both in air and in the sample melt to calculate the buoyancy, B_i , whereas the volume of the bob, V_{bob} , is known. This concept is expressed by Eq. (10) (Keene and Mills, 1995):

$$\rho = \frac{B_i}{V_{\text{bob}}}, \quad (10)$$

More carefully, the surface tension of the melt is also applied to the wire that is used to suspend the bobs. To remove the effect of surface tension on the measured mass of the bob in the melts, two bobs with different sizes are used. This method is called the double-bob Archimedean method. The density of the melt is determined using Eq. (11) (Arman and Takebe, 2019; Bockris *et al.*, 1956):

$$\rho = \frac{B_1 - B_2}{V_1 - V_2}, \quad (11)$$

where B_1 and B_2 represent the buoyancies and V_1 and V_2 are the submerged volumes of the large and small bobs, respectively. The effect of thermal expansion for the bobs is given by Eq. (12):

$$V_1 - V_2 = (V_1' - V_2') \cdot (1 + 3\alpha \Delta T), \quad (12)$$

where V_1' and V_2' are the submerged volumes of the large and small bobs at room temperature and are determined using distilled water. Parameters α and ΔT are the linear expansion coefficient of the contact material and the difference between the examined temperature and room temperature, respectively. For the contact material, platinum group metals (e.g., Pt, Ir, Pt–Rh alloy) are appropriate for most molten oxides. Pt or Pt–Rh has typically been used at temperatures below 1873K. For the higher temperature range, Dingwell (1991) successfully measured the density up to 2200K using Ir contact materials. Mo and W perform better than Pt for systems containing high content of FeO (Biggar, 1970), whereas Mo, BN (or BN-lined graphite) is appropriate for oxynitride melts (Ali *et al.*, 2015; Hampshire and Pomeroy, 2008); however, these contact materials require lower oxygen partial pressures. Theoretically, this method works very well for most molten oxides. However, when the sample is very viscous (e.g., $\eta > 10$ Pa s), it is not easy to accurately measure the density without completely eliminating the convection flow in the crucible. Shartsis and Spinner (1951) evaluated the density of the melt with viscosity up to 500 Pa s using a counterbalanced sphere method, which is also based on the Archimedean principal.

Fig. 8 Schematic of the principle of the (a) conventional and (b) constrained sessile drop methods. Parameters θ and θ_a show the equilibrated and apparent contact angles, respectively.

Sessile drop method

The sessile drop method is a standard method to determine a sample (liquid) shape on a substrate using optical observation. **Fig. 8(a)** shows a schematic illustration of the principle of the sessile drop measurement. The liquid shape is observed in the horizontal direction. Using a two-dimensional image of the liquid shape, the sample volume, V , is calculated from the rotational symmetry around the Z -axis. Therefore, for accurate measurements, the symmetry of the liquid shape should be carefully examined. Techniques for substrate rotation or observations from multiple directions have been developed for this purpose. The sessile drop method works even for more viscous melts ($\sim 10^{12}$ Pa s), as long as the liquid shape (i.e., volume) is clearly observed. However, it is necessary to find substrates that are less reactive and have poor wettability (i.e., contact angle is as high as possible) to the sample melts at elevated temperatures to improve measurement accuracy. Unfortunately, the contact angle of the molten oxide against less reactive materials (e.g., Pt, Rh, Pt–Rh, Mo, W) is not typically high enough ($< 90^\circ$) (Tashiro *et al.*, 2017; Volpe *et al.*, 1959) because the surface energies of these metals are high (> 1500 mN m $^{-1}$). The wettability of graphite (or boron nitride) by molten oxide is normally poor (contact angle $> 90^\circ$) (Eustathopoulos *et al.*, 1999); however, their reactivity to the samples should be carefully tested. Another possibility is the constrained sessile drop method (Duchesne and Hughes, 2017), which has been recently developed to increase the apparent contact angle with respect to the substrate for greater measurement accuracy (**Fig. 8(b)**); this would expand the applicability of the sessile drop method.

Levitation methods

As explained in the section on viscosity measurements, the advantages of levitation techniques are the maximum melting temperature (e.g., ~ 3500 K when using two 100 W CO $_2$ lasers (Kondo *et al.*, 2019)), avoidance of an interfacial reaction, and high degree of supercooling. Therefore, the levitation method has been especially successful for measurements in ultra-high temperature ranges (e.g., > 2200 K), where achieving accurate measurements using container-based methods is difficult owing to the challenge of finding appropriate contact materials to hold molten oxides at such high temperatures. Most molten oxides are levitated through magnetic (Kitamura *et al.*, 2000), electrostatic (Tamaru *et al.*, 2018), or aerodynamic (Nordine *et al.*, 2000; Rajavaram *et al.*, 2019) methods. To measure density by a levitation method, accurate measurement in a sample volume is essential. Electrostatic levitation has the advantage of accurate observation of the liquid shape because the sample is fully visible (Kohara *et al.*, 2014); in aerodynamic levitation, the sample is partly hidden because of a nozzle. However, in recent studies, techniques have been developed to improve the accuracy of estimating the shape of aerodynamically levitated samples (Nakamura *et al.*, 2019). More detailed information on the methodology and limitations of levitation methods are summarized in excellent review papers (e.g., Kargl *et al.*, 2015).

The measurement techniques should be appropriately selected depending on the sample properties, such as viscosity, reactivity against contact materials, and melting point. In particular, the viscosity of molten oxide changes by more than 12 orders of magnitude, depending on the temperature and composition. **Fig. 9** shows a change in the applicable techniques to determine the sample density as a function of melt viscosity. The double-bob Archimedean method enabled the reliable measurement of the liquid density for melt with relatively low viscosities (e.g., < 10 Pa s) as long as the convection flow in the crucible is sufficiently minimized. The double-bob Archimedean and MBP methods work for a similar viscosity range. For a more viscous liquid, the sessile drop method would function more optimally. Levitation methods theoretically enable the measurement of the sample density, regardless of the viscosity or melting point of the sample. However, it is necessary to carefully check the sample temperature and its homogeneity as well as the change in composition of the sample during the measurements because some of the components can easily evaporate from the melts.

Characterization Procedure for Density Data

The importance of density in industrial processes is described in the introduction. However, density is also a useful physical property for characterizing the melt structure, that is, the packing state of the melts. Since density depends on both the packing structure of the melt and the molecular weight of the components, it is converted into molar volume using Eq. (13) to characterize the melt structure.

$$V_m = \frac{\sum x_i \cdot M_i}{\rho}, \quad (13)$$

where x_i and M_i represent the molar fraction and molar weight (10^{-3} kg mol $^{-1}$), respectively, of component i . Alternatively, the

Fig. 9 Applicable viscosity ranges for melt density measurement techniques. (a), (b), and (c) were obtained from the literature. DBA: Conventional applicable range by the authors; MBP: Applicable range reported by Bradley Jr.; Dilatometer: Conventional applicable range by Mazurin. Reported by Bradley Jr, C.A., 1938. Measurement of surface tension of viscous liquids. *Journal of the American Ceramic Society* 21, 339–344. Mazurin, O.V., 2005. Density of glass melts. In: Pye, D., Joseph, I., Montenero, A. (Eds.), *Properties of glass forming melts*. Boca Raton: CRC Press, pp. 193–225.

atomic number density, n (m^{-3}), is derived from Eq. (14) using V_m :

$$n = \frac{N_A}{V_m}, \quad (14)$$

where N_A is Avogadro's number ($= 6.02 \times 10^{23}$). Theoretically, a more detailed packing structure could be described using the ionic packing fraction, V_p , which is estimated by Eq. (15):

$$V_p(\%) = \frac{\sum v_k \cdot m_k \cdot N_A}{V_m} \times 100, \quad (15)$$

where v_k and m_k are the ionic volume (m^3) and atomic fraction, respectively, of the ionic component k . To accurately estimate the V_p value, it is essential to accurately know the ionic volume, which would be obtained by X-ray or neutron scattering experiments. Recently, normalized number density has also been used to interpret the packing structure of oxide glasses and melts under high-pressure conditions (Salmon *et al.*, 2012; Wang *et al.*, 2014).

In the present section, the density of the binary alkali silicate system $\text{R}_2\text{O}-\text{SiO}_2$ ($\text{R} = \text{Li}, \text{Na}, \text{or K}$), a fundamental system used in industries that operate at high temperatures, is chosen as an example. Fig. 10(a) shows the density of binary alkali silicate systems reported by Bockris *et al.* (1956). The density decreases with the addition of all types of alkali oxides. To consider the melt structure, V_m was derived from the density data (Fig. 10(b)). V_m decreases with the addition of Li_2O , whereas V_m increases with increasing K_2O concentration. The additive effect of Na_2O on V_m is small. Similarly, n increases with increasing Li_2O concentration, indicating that Li_2O makes the structure dense (Fig. 10(c)). In the $\text{K}_2\text{O}-\text{SiO}_2$ system, the atomic distribution is sparser than that for $\text{Li}_2\text{O}-\text{SiO}_2$ or $\text{Na}_2\text{O}-\text{SiO}_2$ systems because the partial molar volume of potassium oxide ($\approx 50 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1}$) is larger than that of sodium oxide ($\approx 30 \times 10^{-6} \text{ m}^3 \text{ mol}^{-1}$) (Yang *et al.*, 2019). V_m and n depend strongly on the size of alkali cations and open space in the network structure, while the size of the SiO_4 tetrahedron hardly changes depending on the type of alkali oxide (Saito *et al.*, 2016; Waseda and Suito, 1977). A detailed characterization of the three-dimensional structure of silicate melts is required to fully understand the change in V_m depending on the concentration and type of alkali cations. State-of-the-art approaches such as synchrotron X-ray scattering coupled with reverse Monte Carlo simulation would be helpful in revealing the packing state of the melt in detail (Kohara *et al.*, 2014).

Density measurements have been performed for many types of oxide systems, with density data available in papers, books, and databases (see further reading section).

Surface Tension

The atoms in the liquid bulk tend to satisfy their chemical interactions with their nearest neighbors, whereas surface atoms often lack neighboring atoms. The resulting unsaturated bonds at the surface lead to excess energy, which is the origin of surface tension. Because liquids tend to minimize their surface area to reduce excess energy γ , they should reflect the state of chemical bonds at the liquid surface; in other words, γ should increase with an increase in the number of unsaturated bonds. The dimension of γ is expressed by the ratio of energy to area (J m^{-2}); however, the unit (N m^{-1}) is more typically used as the dimension (because $1 \text{ J} = 1 \text{ N m}$). In industrial processes, surface tension is also an important physical property when we consider the phase-separating processes (e.g., gas/liquid, liquid/liquid, and liquid/solid) as well as the wetting and spreading behavior of molten oxides on a solid phase at elevated temperatures. Accordingly, knowing the γ of molten oxide is essential for understanding the structure of molten oxide around the surface as well as for controlling the high-temperature processes. In the present section for surface tension, the measurement techniques and interpretation of γ of molten oxides at temperatures above their liquidus are explained.

Fig. 10 Example of conversion of (a) density, ρ , data into (b) molar volume, V_m , or (c) number density, n , for binary alkali silicate melts. Original data from Bockris, J.O.M., Tomlinson, J.W., White, J.L., 1956. The structure of the liquid silicates: Partial molar volumes and expansivities. Transactions of the Faraday Society 52, 299–310.

Measurement Methods

Measurement techniques for liquid surface tension are composed of static and dynamic methods. Sessile or pendant drop methods are categorized as static methods, whereas ring methods (similar to the dipping cylinder method) or the MBP method are dynamic methods. Recently, levitation techniques have also been used to determine the surface tension. Because the ring method and MBP methods are frequently employed for molten oxides, we explain the details of these two conventional methods and recent levitation techniques for surface tension measurements.

Ring method

The ring method evaluates the surface tension, γ , by measuring the force required to detach a ring from the liquid surface. The principle of this method is similar to that of the dipping cylinder method (Babcock, 1940) and is illustrated in Fig. 11(a). The force has a maximum value ($w_{\max}$) when the contact angle θ is zero. Fig. 11(b) shows a typical example of evolution of the force value during the ring-pulling process. The γ parameter is expressed by Eq. (16) (Hwang *et al.*, 2012; Shimizu *et al.*, 2006):

$$\gamma = \frac{w_{\max} \cdot g}{4\pi R_0(1 + \alpha \Delta T)} \cdot S \quad (16)$$

where R_0 is the radius of the ring, α is the linear expansion coefficient of the ring material, ΔT is the difference between the room and examined temperature, and S is an empirical correction factor known as the Harkins and Jordan correction factor (Harkins and Jordan, 1930). S is a linear function of the ratio of the maximum force to the melt density ($w_{\max}/\rho$), which depends on the size and shape of the ring. In general, the relationship between S and $w_{\max}/\rho$ is determined using several types of reference materials (e.g., molten salts and room temperature liquids). The ρ and γ parameters of the reference materials should be known values (Hwang *et al.*, 2004). The principle of the ring method is simple and it enables us to measure γ accurately. A limitation of this method is that application to a highly viscous system (e.g., $\eta > 200$ Pa s) is difficult (Babcock, 1940). Moreover, this is also a container-based technique; thus, selecting an appropriate contact material is important for minimizing the reactivity of contact materials against a sample melt at the given temperatures.

Fig. 11 (a) Schematic of the principle of the ring method. F depicts the force applied on the ring by the surface tension of the melt. (b) Evolution of detected electrical voltage by a strain gauge during the ring-pulling process where a calcium aluminosilicate melt sample was used. The detected voltage was linearly correlated with the force. (a) Redrawn from Saito, N., 2005. Fundamental Study on Liquid Phase Sintering Process of Silicon Nitride Ceramics. Doctoral dissertation. Kyushu University. (b) Redrawn from the authors' unpublished work.

Fig. 12 Schematic for the principle of the MBP method. Figure is redrawn from Fukuta, M., Sumiyama, J., Motozawa, M., Yanagisawa, T., 2017. Surface tension measurement of oil/refrigerant mixture by maximum bubble pressure method. International Journal of Refrigeration 73, 125–133.

MBP method

Fig. 12 illustrates the principle of the MBP method. The MBP method evaluates the surface tension of the melt by monitoring the gas pressure $P_{\max}$, which is required for a bubble to break away from the tip of the capillary tube (commonly made of Pt or Ni) immersed in melts. The pressure in the capillary P is calculated by Eq. (17):

$$P = \rho gh + \frac{2\gamma}{r} \quad (17)$$

where ρ is the density of the melt, g is the gravitational acceleration, h is the immersed depth of the capillary, γ is the surface tension, and r is the radius of curvature of the bubbles. P has a maximum value, $P_{\max}$, when the bubble radius r is equal to the inner radius of the capillary (see **Fig. 12**). The detailed procedure is explained by [Takeda et al. \(2017\)](#). In addition to the ring method, the MBP method is a well-established technique for the low viscosity range ($\eta < 50$ Pa s) ([Bradley Jr., 1938](#)). For liquids with higher viscosities, static techniques (sessile drop or pendant drop method) should be used ([Ellefson and Taylor, 1938](#); [Kingery, 1959](#)). The static techniques are well summarized in textbooks (see further reading section).

Levitation technique

As explained in the “Viscosity” and “Density” sections, the levitation technique has expanded the applicable temperature range of the surface tension measurement. Rayleigh (1879) calculated the oscillation frequencies, ω_l , of a non-viscous, force-free liquid using Eq. (18) (Egry *et al.*, 2005, Langstaff *et al.*, 2013):

$$\omega_l^2 = l(l-1)(l+2) \frac{4\pi}{3} \frac{\gamma}{M} \quad (18)$$

where $l (\geq 2)$ is an integer and M is the mass of the droplet. For $l = 2$, ω_l has the lowest value, which is called the Rayleigh frequency. To measure ω_l , an acoustic oscillation generator has been typically used, as employed in the “viscosity” measurements (see Fig. 4). To measure the γ of molten oxides, several types of levitation techniques (e.g., aerodynamic levitator or electrostatic levitation techniques) have been used. In addition, γ has been reported for refractory melts (e.g., Al_2O_3 (Glorieux *et al.*, 2002)). Since Eq. (13) is only applicable for non-viscous systems, the levitation technique is difficult to apply to highly viscous melts; in addition, the applicable viscosity range of levitation techniques has not yet been reported in detail. As discussed for the viscosity and density measurement techniques, the measurement method for the melt surface tension also depends on the viscosity range of the melts. Fig. 13 illustrates the conventional applicable viscosity range of several types of measurement techniques for surface tension.

Interpretation of Melt Surface Tension

The surface tension, γ , of molten oxides depends on the structural difference between the bulk and the surface. Generally, the γ of a liquid increases as the bond strength and the number of unsaturated bonds at the liquid surface increase. Structural characterization techniques for high-temperature melts have been developed for Raman, NMR, and synchrotron X-ray spectroscopy and neutron scattering (e.g., Henderson *et al.*, 2014). However, understanding the surface structure of molten oxides remains difficult. Livey and Murray (1956) suggested that the surface of the molten oxides is mainly composed of oxygen atoms. This hypothesis has not been directly proven; however, it has been consistent with the surface tension of molten oxides. Boni and Derge (1956) related the γ of several types of molten pure oxides (i.e., single component) to the ionic potential (Z/r_i , r_i : ionic radius, Z : valence number), which is a measure of the charge density at the surface of the cations. Fig. 14 shows this relationship. Following the hypothesis of Livey and Murray, this trend should reflect the local structure of oxygen atoms around the melt surface. The surface tensions of monovalent or divalent metal oxides tend to increase with increasing ionic potential. This tendency can be explained by an increase in the bond strength between oxygen and the cation by the increasing Z/r_i when the number of unsaturated bonds is assumed to be comparable. It should also be noted that the surface tension of molten oxide for intermediate cations (e.g., Al^{3+}) is higher than that of framework cations (e.g., Si^{4+}). This phenomenon indicates that the surface oxygen atoms in an Al_2O_3 melt have a stronger tendency to lose their neighboring cations, compared with SiO_2 or B_2O_3 melts; these network liquids would satisfy the chemical bond at their melt surfaces more easily, as suggested by Kingery (1959). To understand the γ for multi-component systems (systems with more than two components), it is necessary to consider the presence of at least three types of oxygen atoms: bridging-, nonbridging-, and free-oxygen atoms. It has been reported that the γ of the four-component $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-MgO}$ melts increases with an increase in the number of nonbridging oxygens or the number of Al cations in the network structure (Sukenaga *et al.*, 2015). This phenomenon can be explained by the coordination structure of oxygen atoms (see Fig. 15). In the

Fig. 13 Applicable viscosity ranges for surface tension measurement techniques. Fig. 15 Schematic illustrations of the local structure for three types of oxygen atoms in the bulk and at the melt surface. The Al coordination is assumed to be tetrahedral. The coordination numbers of (a) Si–O_{BO}–Si, (b) Si–O_{BO}–Al, and (c) Si–O_{NBO} are drawn as 2, 3 and 4, respectively. Figure is redrawn from Sukenaga, S., Higo, T., Shibata, H., Saito, N., Nakashima, K., 2015. Effect of CaO/SiO₂ ratio on surface tension of CaO–SiO₂–Al₂O₃–MgO melts. ISIJ International 55, 1299–1304.

bulk melt, a nonbridging oxygen (Si–O_{NBO}) and bridging oxygen between Si and Al atoms (Si–O_{BO}–Al) tend to have higher coordination number than that of a bridging oxygen between two Si atoms (Si–O_{BO}–Si). These oxygens with higher coordination number will have stronger tendency to lose their neighbors at the melt surface. To better understand γ for multicomponent oxide melts, characterization techniques for the surface structure should be developed in future studies.

Concluding Remarks and Further Reading

In the present chapter, we summarize the measurement techniques (including recent levitation techniques) and a typical procedure for the interpretation of three physical properties, viscosity, density, and surface tension of oxide melts, particularly at temperatures above their liquidus. Other physical properties, such as heat capacity, thermal and electrical conductivities, electrical capacitance, and diffusivity are also very important for controlling industrial processes and understanding the structure of melts at elevated temperatures. The authors believe that one of the important goals of the measurement of physical properties is to understand how each component is mixed together in the melts at elevated temperatures, because this understanding will directly

lead to an in-depth understanding of the melt structure and the establishment of a reliable estimation model for the properties. To achieve this, it is necessary to continue and expand these physical property measurements for a wide variety of compositions and temperature ranges. Recent structural analyses of molten oxides support this understanding (e.g., Alderman *et al.*, 2014; Florian *et al.*, 2018; Kanehashi and Stebbins, 2006; Maehara *et al.*, 2004). There are excellent texts and reviews that address how to measure and understand the properties of high-temperature melts. Detailed information on measurement techniques and the measured physical properties for a wide range of compositions can be found in the following references.

Overview: Mechanical and Physical Properties and Property Testing of Ceramics and Glasses

Anne Leriche, Polytechnic University Hauts-de-France, Valenciennes, France

Francis Cambier, Belgian Ceramic Research Centre, Mons, Belgium

© 2021 Elsevier Inc. All rights reserved.

The properties of ceramic materials and glasses depend mainly on the types of atoms that compose them, their structural organization and the types of bonds between these atoms. Chemical bonds in ceramic and glassy materials are ionic and/or covalent. Such bonds are much stronger than metallic bonds, which explain, in general, why ceramics have particular properties. A key point is that metals are ductile and ceramics are brittle. This does not mean that the ceramic cannot withstand any stress, it means that on a given stress (critical stress), the failure is in general “catastrophic” (that is to say at the speed of sound). However, on the one hand this critical stress can be enormous and on the other hand there are many ways to improve the behavior of ceramic parts placed under aggressive loads.

Ceramics and glasses are used for numerous applications due to their wide range of special properties. In this section devoted to “Mechanical and Physical Properties and Property Testing of Ceramics and Glasses”, the following points will be described and discussed: elasticity, hardness, wear behavior (part A); flexural strength, toughness, crack growth, toughening, microstructure influence (part B); thermal behavior, creep, dislocations, corrosion (part C).

Part A: this sub-section comprises 3 chapters.

The first is devoted to the elastic or inelastic behavior of ceramics; the second describes in detail the hardness and the many methods commonly used to measure this quantity, finally the third chapter is devoted to the tribological behavior and to the wear resistance of ceramic-carbon composites.

Part B: In a first approach, it can be considered that ceramics and glasses follow the concept of linear mechanic of rupture. That means that the rupture of a ceramic or a glass will occur from an pre-existing defect located somewhere in the body or at its surface (it is called the critical defect). Under the effect of a stress concentrated around this defect, the defect size will increase at a given speed, as a function of the magnitude of the stress and of the environment. The two first chapters of this subsection deal with measurement, on the one hand of elastic modulus and tensile, flexural, compressive strength, on the other hand of fracture toughness. Then, one chapter concerns the increase of growth resistance as the crack extends (called R-curve behavior) and two chapters deal with the various aspects of the phenomenon of subcritical growth (basic relations, measurement and modeling). The three last chapters are devoted to examples as the transformation toughening with zirconia, as the mixed mode fracture or as the microstructural aspects on crack propagation.

Part C: historically, the first applications of technical ceramics were as refractory materials; this is why this subsection takes into account this important aspect (6 chapters). The three first chapters concerns thermal shock. After a general overview of thermal properties, thermal shock behavior is first discussed on the fundamental point of view introducing the thermal shock parameters; then through examining the thermal fatigue and the effect of the microstructure. Creep is also defined and presented both for oxide and for some non oxide ceramics (2 chapters). Then one chapter is devoted to movement of dislocations; finally, this section ends by 2 chapters concerning corrosion and degradation of ceramics and glasses, these last mostly in aqueous environment.

Elastic and Inelastic Behavior of Ceramics

Introduction

Ceramics are generally considered as refractory materials resisting plastic deformation even at high temperature. In ceramics, we find elastic moduli, which are much higher than in metals. Moreover, ceramics and oxides generally own a low density. Therefore, the ratio between the modulus and the density, which is often searched for mechanical and structural applications, is generally very high. Some mechanical properties are summarized in [Table 1](#).

At room temperature, technical ceramics are generally brittle. As shown in [Table 1](#), their toughness hardly passes 5 MPa·m. In this case, zirconia owns a particular interest since the addition of yttria produces toughening levels unattained by other ceramics ([Marshall et al., 1983](#)).

However, limited plasticity appears in most ceramics at a temperature that can be defined as a brittle-to-ductile transition temperature. High temperature plastic deformation of fine-grained ceramics, such as Al_2O_3 , ZrO_2 , or Si_3N_4 , has been usually interpreted as due to grain boundary (GB) sliding ([Wakai et al. 1986](#); [Carry and Mocellin, 1987](#); [Duclos et al., 1989](#); [Boutz et al., 1994](#)).

In many cases, GB sliding is lubricated by an amorphous inter-granular phase, which results from the presence of sintering aids, and undergoes a glass transition at high temperature ([Rouxel and Wakai, 1993](#)). Extensive GB sliding without cavitation needs accommodation processes such as volume diffusion (Nabarro-Herring creep ([Herring, 1950](#))) or GB diffusion (Coble creep ([Coble, 1963](#))). Theoretical models have been developed to predict the values of parameters entering the standard equation for the creep rate

$$\dot{\epsilon}(\sigma, T) \approx \left(\frac{\sigma}{G}\right)^\eta \cdot \left(\frac{b}{d}\right)^p \cdot D_0 \cdot e^{-\frac{H}{RT}} \quad (1)$$

where G is the sliding modulus, b the Burgers vector, D_0 limit diffusion coefficient, σ the applied stress, n the stress exponent, d the mean grain size, p the grain size exponent, H the activation enthalpy and R gas constant.

Anelastic deformation i.e., reversible non-linear deformation precedes plastic deformation and consequently it may be the first manifestation of the brittle-to-ductile transition in ceramics. Mechanical spectroscopy ([Schaller et al., 2001](#)), is based on anelasticity ([Nowick and Berry, 1972](#)); it consists in measuring the internal friction i.e., the damping capacity or mechanical loss of materials. It is very sensitive to all microstructure changes, and it is well suited for studying a brittle-to-ductile transition, in which energy dissipation is involved. For instance in zirconia, GB sliding gives rise to a mechanical loss peak, which evolves in an exponential background at higher temperature ([Lakki et al., 1993](#)). The higher the amount of inter-granular glassy phase, the higher is the level of the exponential background and consequently the creep rate.

Anelasticity and Mechanical Spectroscopy

Anelasticity ([Nowick and Berry, 1972](#)) appears in the following simple experiment ([Fig. 1\(a\)](#)). A stress σ , of low amplitude, is applied abruptly to a specimen at time, $t = 0$, and held constant while the strain, ϵ , is recorded as a function of time.

It can be observed ([Fig. 1\(a\)](#)) that the instantaneous elastic strain, $\epsilon_e = J_u \sigma$, where J_u is the unrelaxed compliance, and the anelastic strain ϵ_a , increases with time from zero to an equilibrium value. When equilibrium is reached, $\epsilon = \epsilon_e + \epsilon_a^\infty = J_r \sigma$ where J_r is the relaxed compliance. This evolution from one equilibrium state to a new one, under an applied stress, is called anelastic relaxation, and may be defined by two parameters, the relaxation time τ and the relaxation strength Δ :

$$\Delta = \frac{\epsilon_a^\infty}{\epsilon_e} = \frac{J_r - J_u}{J_u} \quad (2)$$

If, the stress is removed after a certain delay, one can observe the instantaneous recovery of the elastic strain and, within the relaxation time τ , the recovery of the anelastic strain. In such an experiment, the strain is completely recoverable.

Table 1 Mechanical properties of some technical ceramics

	Young's Modulus [GPa]	Poisson's ratio	Density [Kg/dm ³]	Toughness [MPa·√m]
Al_2O_3	270–390	0.22–0.27	3.5–3.9	2.7–4.8
ZrO_2 (3%Y)	200–250	0.30–0.32	5.9–6.1	6.0–8.0
Si_3N_4	290–320	0.26–0.28	3.1–3.4	4.0–6.7
SiC	400–460	0.16–0.18	3.1–3.2	3.0–5.6

Fig. 1 (a) Elastic ϵ_e and anelastic ϵ_a strain of a solid submitted to stress σ . (b) Rheological model corresponding to the anelastic behavior of Fig. 1a.

From a microscopic point-of-view, anelastic strain can be interpreted as being due to the movements of structural defects (elastic dipoles, dislocations, interfaces, grain boundaries) from one equilibrium position defined at $\sigma = 0$ to another one defined at σ_0 . The relaxation strength, Δ , is then proportional to the concentration of defects, which are relaxing; the relaxation time τ accounting for their mobility.

From a rheological point-of-view, the solid can be represented by the model shown in Fig. 1(b). The spring " $J_r - J_u$ " in parallel with the dashpot of viscosity η is essential to the recoverable nature of the anelastic strain. If this spring does not operate, the anelastic strain does not reach an equilibrium value and then it is no longer completely recoverable: creep occurs.

The anelastic behavior in Fig. 1 is representative of the standard anelastic solid, the equation of which is:

$$\epsilon + \tau \cdot \dot{\epsilon} = J_r \cdot \sigma + \tau \cdot J_u \cdot \dot{\sigma} \quad (3)$$

Measurements performed as described in Fig. 1 are very delicate, and in practice, it is more convenient to use dynamic methods for measuring the relaxation parameters. If an alternated stress, of circular frequency ω , $\sigma = \sigma_0 \exp(i\omega t)$ is applied to the system, the linearity of the stress-strain relationships insures that strain ϵ is periodic with the same frequency: $\epsilon = \epsilon_0 \exp[i(\omega t - \phi)]$, where ϕ is the phase lag of strain behind stress (due to anelasticity). Introducing these expressions of σ and ϵ in Eq. (3) leads to the following relationship:

$$\epsilon = \left[\left(J_u + \frac{J_r - J_u}{1 + \omega^2 \tau^2} \right) - i \cdot \left(\frac{(J_r - J_u) \cdot \omega \tau}{1 + \omega^2 \tau^2} \right) \right] \cdot \sigma = [J_1(\omega) - iJ_2(\omega)] \cdot \sigma = J^*(\omega) \cdot \sigma \quad (4)$$

where J_1 and J_2 are, respectively, the real and the imaginary part of the complex compliance J^* .

In metals and ceramics $J_r - J_u \ll J_u$, and the mechanical loss angle ϕ is given by:

$$\tan \phi = \frac{J_2}{J_1} = \Delta \frac{\omega \tau}{1 + \omega^2 \tau^2} \quad (5)$$

and the variation of the dynamical compliance $\frac{\Delta J}{J}$ due to anelasticity by:

$$\frac{\delta J}{J} = \frac{J_1(\omega) - J_u}{J_u} = \Delta \frac{1}{1 + \omega^2 \tau^2} \quad (6)$$

Mechanical loss, $\tan \phi$, presents a maximum as a function of $\omega \tau$, centered at $\omega \tau = 1$. This maximum or peak gives us the relaxation strength, Δ , (height of the peak) and the relaxation time, τ , (position of the peak on the $\omega \tau$ axis). If several relaxation mechanisms are activated, the material exhibits a mechanical loss spectrum composed of damping peaks, which give information about the microstructure dynamics. Since, most of the relaxation mechanisms are thermally activated,

$$\tau = \tau_0 \cdot \exp(H/kT) \quad (7)$$

H being the activation enthalpy and τ_0 the limit relaxation time.

As a consequence, $\tan \phi$ can be also measured as a function of temperature holding ω constant and the curve $\tan(\phi) = \tan(\phi(T))$ is the mechanical loss spectrum described as a function of temperature. A maximum (peak) in the mechanical loss may appear at the frequency ω_p and temperature T_p under the condition that:

$$\omega_p \tau = \omega_p \tau_0 \cdot \exp\left(\frac{H}{kT_p}\right) = 1 \quad (8)$$

The activation enthalpy can be obtained by drawing an Arrhenius plot, in which $\ln \omega$ is reported as a function of the inverse of temperature (T_P^{-1}):

$$\ln \omega_p = -\ln \tau_0 - \frac{H}{k} \cdot \frac{1}{T_P} \quad (9)$$

The internal friction IF is defined as:

$$IF = \frac{1}{2\pi} \cdot \frac{W_{diss}}{W_{el}} \quad (10)$$

where W_{diss} is the energy dissipated in a volume unit during one cycle of vibration and W_{el} is the maximum stored elastic energy per unit volume.

$$W_{diss} = \oint \sigma \cdot d\varepsilon = \pi \cdot \sigma_0 \cdot \varepsilon_0 \cdot \sin \phi = \pi \cdot J_2 \sigma_0^2 \quad (11)$$

$$W_{el} = \int_0^{\sigma_0} \sigma \cdot d\varepsilon = \frac{1}{2} J_1 \sigma_0^2 \quad (12)$$

It follows immediately that:

$$IF = \tan \phi \quad (13)$$

Mechanical Spectrometer: Torsion Pendulum

For low frequency and particularly for high temperature the most commonly used apparatus for mechanical spectroscopy is the inverted torsion pendulum (Fig. 2, and (Gadaud *et al.*, 1990)). The sample, a wire or a plate (1), is placed in the center of a regulated furnace (2). The torsion excitation stress is applied to the pendulum axis by means of Helmholtz coils (3) acting on a permanent magnet fixed on the upper part of rod. Strain is measured by the deflection by a mirror of a laser beam (4) reflected onto a linear photo-detector (5). The whole apparatus is maintained under secondary vacuum (10^{-3} Pa) by a diffusion and a primary rotary pump.

Experimental Data

Two ceramics, differing by their microstructure (Fig. 3), which have been studied by mechanical spectroscopy are presented here as examples.

Fine-grained zirconia (3Y-TZP): fully tetragonal zirconia stabilized by 3 mol% of yttria) exhibits a microstructure of equiaxed grains with a mean diameter of 0.29 μm (Fig. 3(a)).

Silicon nitride (Si_3N_4) specimens exhibit a mixture of two kinds of grains: elongated and equi-axed (Fig. 3(b)). A relatively large volume fraction of glassy phase can be detected in these ceramics as inter-granular films or as pockets at the triple points.

Mechanical spectroscopy measurements were performed with a forced torsion pendulum as described in Fig. 2. With this apparatus, the mechanical loss angle ($\tan \Phi$) and the shear modulus (G) are obtained from the phase lag and the amplitude ratio between stress and strain, respectively. Measurements are performed under vacuum (10^{-3} Pa) as a function of temperature (300–1600K) at a fixed frequency, or as a function of frequency (10^{-3} –10 Hz) at fixed temperature.

Mechanical Spectroscopy of Zirconia

Fig. 4 shows a typical mechanical loss spectrum ($\tan \phi$ and elastic shear modulus $G = 1/J$) measured as a function of temperature in fine-grained zirconia (2Y-TZP): fully tetragonal zirconia stabilized by 2 mol% of yttria (Lakki *et al.*, 1993). The mechanical loss spectrum of TZP zirconia is composed of a damping peak at about 350K, associated with a modulus defect, and of an exponential increase in damping associated with a steep decrease in the shear modulus at high temperature.

Low Temperature Peak

The mechanical loss peak at 350K and the modulus variation occur as well in temperature measurements (with practically no hysteresis between heating and cooling curves (Fig. 5(a))), and in frequency measurements (Fig. 5(b)). They are, therefore, manifestations of the same relaxation phenomenon, which is found to be thermally activated. By using the data concerning the “frequency-temperature” peak locations, an Arrhenius plot can be drawn (Fig. 6).

The activation enthalpy, H_{act} , of this relaxation was found to be 0.97 ± 0.03 eV (89 kJ/mol) and the limit relaxation time, τ_0 , is equal $\approx 0.7 \cdot 10^{-14}$ s. These values characterize a point defect relaxation mechanism.

Fig. 2 Schematic drawing of an inverted forced torsion pendulum: (1) sample, (2) furnace, (3) excitation system “magnet- Helmholtz coils”, (4) laser and (5) photocells.

Fig. 3 (a) Granular microstructure of 3Y-TZP zirconia. (b) Microstructure silicon nitride with elongated and equiaxed grains (dark phase) surrounded by a glassy phase (white).

The current interpretation (Weller, 1994) invokes the reorientation of elastic dipoles of the type “oxygen vacancy-yttrium cation” under the influence of the applied stress (Fig. 7). Peak-broadening may be due to additional contributions of more complex clusters, e.g., two Y^{3+} ions and one O^{2-} vacancy. Since the elastic dipoles are at the same time electric dipoles, giving rise to a dielectric loss peak as well, this effect is important in the study of the ionic conductivity of zirconia.

In order to determine the origin of the high temperature damping, it is possible to compare the mechanical loss spectrum of the ceramic with the spectra of the components: grains and GBs. For zirconia, the comparison in Fig. 8 of the high temperature spectra of poly- and single-crystals shows clearly that the high temperature background is due to GBs.

Fig. 4 Mechanical loss ($\tan \phi$) and elastic shear modulus (G) as functions of temperature in 2Y-TZP zirconia.

Fig. 5 Low temperature mechanical loss peak and modulus variation in zirconia. (a) as a function of temperature (measurements during heating and cooling) and (b) as a function of frequency.

Fig. 6 Arrhenius plot from the "frequency-temperature" shifts of the low temperature peak in zirconia: $H_{\text{act}} = 0.93 \text{ eV}$ (89 kJ/mol), $\tau_0 \approx 0.7 \cdot 10^{-14} \text{ s}$.

The combining of dielectric and anelastic relaxation measurements in the study of point defects in insulating crystals J. Phys. Colloques 46 (C10), C10-507–C10-511.

Fig. 8 Mechanical loss as a function of the temperature in a poly-(dots) and in a single-crystalline zirconia (markers).

Fig. 9 Comparison of the high temperature behavior of two Y-TZP grades, A and B, which differ mainly in their impurity content: (a) Mechanical loss $\tan \Phi$ and shear modulus G as functions of temperature (frequency $f = 1$ Hz, heating rate 1 K/min). (b) Creep rate measured at 1623 K under a stress of 10 MPa as a function of time. Adapted from Lakki, A., Schaller, R., Nauer, M., Carry, C., 1993. High temperature superplastic creep and internal friction of yttria doped zirconia polycrystals. Acta Metall. Mater. 41, 2845–2853.

Fig. 9(a) displays the typical spectra of two zirconia grades A and B, which have almost the same grain size and differ only with respect to the impurity content (and therefore have a different amount of inter-granular glassy phase). The amplitude of the applied cyclic stress during measurements was of the order of 4 MPa.

Grade A (i.e., with the higher impurity content) shows a faster increase in the mechanical loss and a steeper modulus decrease than grade B. In parallel, grade A exhibits a higher strain rate during creep tests at 1623K in the low stress regime (10 MPa) than grade B (Fig. 9(b)).

The exponential increase in damping associated with the steep decrease in the shear modulus at high temperature accounts for the appearance of ductility in the ceramic material, i.e., a brittle-to-ductile transition. In fact, an exponential increase in $\tan(\phi)$ implies an increase in the anelastic strain, which does not reach an equilibrium value. This means that creep is occurring. The creep rate can be described by the classical Eq. (1):

$$\dot{\epsilon}(\sigma, T) \approx \left(\frac{\sigma}{G}\right)^n \cdot \left(\frac{b}{d}\right)^p \cdot D_0 \cdot e^{-\frac{H_{act}}{RT}}$$

Eq. (1) combined with Eqs. (10) to (13) can be used to calculate the internal friction IF or the mechanical loss $\tan(\phi)$,

$$\tan(\phi) = A \frac{G \cdot \sigma^{n-1}}{\omega \cdot d^p} \exp\left(-\frac{H_{act}}{kT}\right) \quad (14)$$

where G is the shear modulus, ω the circular frequency and A a material constant.

Eq. (14) has an exponential form, which fits well to the experimental results obtained in the high temperature domain where creep is enhanced. Plotting $\ln(\tan(\phi))$ as a function of $1/T$ leads to a straight line (Fig. 10), the slope of which would give the activation enthalpy.

In grade B, a value of $H_{act} = 162$ kJ/mol is obtained by this method. This value is much smaller than the activation enthalpy deduced from creep tests, which was of 620 kJ/mol (Nauer and Carry, 1990). This indicates that the above analysis is simplistic and leads to wrong quantitative values.

A better value for the activation enthalpy may be obtained from a method that is called Master Curve. It consists in shifting frequency spectra obtained in isothermal conditions in order to obtain a unique matching curve. The mechanical loss spectra obtained at different frequencies as a function of temperature are shown in Fig. 10(a). The value for the activation enthalpy is obtained from the Arrhenius plot (Fig. 10(b)) built from the "temperature-frequency" shifts of the mechanical loss spectra (Fig. 10(a)). The obtained value of 634 kJ/mol corresponds well to the one obtained in creep tests.

Grain Size Effect

The influence of the grain size on the mechanical loss spectra is shown in Fig. 11. Three samples with $d = 0.34, 0.69$ and $1.00 \mu\text{m}$ were measured. It is observed that the damping is inversely proportional to " d " as a first approximation. The deduced grain size exponent is found to be about 1. For all grain sizes, the (isothermal) spectra seem to be composed of a peak plus a background. Both the peak height and frequency position decrease with increasing the grain size.

All the above results show that there is a close correlation between the high temperature mechanical loss spectrum of zirconia and its creep behavior: similar values for the activation enthalpy and the grain size exponent. It has been observed that the mechanical loss increases linearly with stress in the low frequency (~ 10 mHz) and high temperature ($\sim 1600\text{K}$) regime for

Fig. 10 (a) High temperature part of the mechanical loss spectrum of the B grade ($d = 0.34 \mu\text{m}$) as a function of temperature at 3 different frequencies. (b) Arrhenius plot for the high temperature part of the mechanical loss spectrum.

Fig. 11 Model of hexagonal grains separated by an inter-granular layer of viscosity η .

stresses higher than 2 MPa. This is in good agreement with Eq. (14) and with the value of the stress exponent $n \sim 2.4$ obtained in creep tests for stresses lower than 15 MPa (Nauer and Carry, 1990).

A theoretical model was developed by Lakki (1994) to account for the mechanical loss due to the relative sliding of grains of hexagonal shape (Fig. 12). If " u " is the relative displacement of two grains, τ the applied shear stress, η the interface viscosity, δ the inter-granular layer thickness and Ku the restoring force due to the limiting grains at triple junctions, the motion equation is:

$$\sigma = \frac{\eta}{\delta} \cdot \dot{u} + K \cdot u \quad (15)$$

The mechanical loss $\tan(\phi)$ is then directly obtained from the phase lag between stress τ and strain ε :

$$\varepsilon = \varepsilon_e + \varepsilon_a = \frac{\sigma}{G} + \frac{u}{d} \quad (16)$$

and, in the case of a harmonic stress, one obtains:

$$\tan(\phi) = \frac{G}{d} \cdot \frac{\omega \cdot \eta / \delta}{\left(\frac{KG}{d} + K^2\right) + (\omega \eta / \delta)^2} \quad (17)$$

$\tan \phi$ has the form of a peak with a maximum at

$$\omega_p = \frac{\delta}{\eta} \cdot \sqrt{\frac{KG}{d} + K^2} \quad (18)$$

However, the high temperature mechanical loss spectrum in zirconia does not exhibit a peak, but an exponential increase with temperature (Fig. 9).

In fact, isothermal measurements performed at 1600K show that the spectrum is composed of a peak and an exponential background at lower frequencies (Fig. 11).

It is possible to account for this spectrum by considering that the restoring force " Ku " is reduced at high temperature, where creep takes place. Assuming that K is proportional to the shear modulus $G(t) = \tau/\varepsilon(t)$, which decreases deeply at high temperature, one can calculate the theoretical spectra presented in Fig. 13(b).

The theoretical model by Lakki allows a good interpretation of the experimental results shown in Fig. 13(a): a grain boundary peak, which evolves into an exponential background at lower frequency. In Fig. 13(a), the finer the grains the higher the mechanical loss peak, in good agreement with Eq. (17). The transition from the peak to the exponential background is due to the decrease in the restoring force factor " K " due to the weakening of the triple points. The deformation is no more reversible, and creep occurs.

Fig. 12 Mechanical loss as a function of frequency, for zirconia of grade B, differing only in the grain size ($d = 0.34, 0.69$ and $1.00 \mu\text{m}$).

Fig. 13 (a) Mechanical loss spectra of 3Y-TZP zirconia measured at 1600K for different grain sizes d . (b) theoretical spectra calculated from Eq. (17) with a decrease of the restoring force K at high temperature.

As a conclusion, an increase in the creep resistance of fine grain ceramics needs to increase the restoring force, which hinders long range GB sliding resulting in a lower high temperature mechanical loss. Such an increase in creep resistance was achieved by Mazaheri *et al.* (2010), who reinforced fine grained zirconia with carbon nanotubes. It was shown that carbon nanotubes were located at the GBs and were able to limit considerably the sliding process. As a matter of fact, Fig. 14 shows that with additions of carbon nanotubes, the high temperature mechanical loss decreases (Fig. 14(a)) and so is the creep rate (Fig. 14(b)).

Mechanical Spectroscopy in Silicon Nitride

In silicon nitride (Si_3N_4), the sintering aids generate an important volume fraction of amorphous phase (YSiAlON glass). This phase is not only located as thin films between the grains, but also at the triple points where large glassy pockets have been observed.

The mechanical loss spectrum of Si_3N_4 shown in **Fig. 15** highly differs from the one of zirconia. The spectrum is composed of a mechanical loss peak located at around 1270K, which is superimposed on an exponential “background” and accompanied by a steep modulus decrease (curves 1 in **Fig. 15**).

The mechanical loss peak and the associated modulus anomaly disappear after thermal treatments, which enhance the crystallization of the glassy pockets (curves 2). This indicates that the peak is due to relaxations in the glassy pockets.

However, if the temperature does not exceed 1200K, the peak is stable and can be measured as a function of temperature under isothermal conditions (**Fig. 16(a)**). The peak is a relaxation peak, because it shifts in frequency when the temperature is modified.

An Arrhenius plot can be drawn (**Fig. 16(b)**) giving a value of 1117 kJ/mol for the activation enthalpy and $0.8 \cdot 10^{-47}$ s for the limit relaxation time.

It is possible to compare the spectrum of Si_3N_4 ceramic with the spectrum of one of the constituents, that is the glassy phase (**Fig. 17**). The mechanical loss in YSiAlON glass increases exponentially at the temperature where the peak is observed in silicon nitride. This increase in damping is due to the α -relaxation in a YSiAlON glass. The α -relaxation can be studied by measuring the real G_1 and imaginary component G_2 of the shear modulus G .

A relaxation peak is observed in the imaginary component G_2 (**Fig. 18**). The activation enthalpy of 1115 kJ/mol obtained from the shifts of the peak is the same as for the peak in Si_3N_4 . This confirms that the peak in Si_3N_4 is due to the α -relaxation in the glassy pockets (Donzel *et al.*, 1997). Near the glass transition temperature, the pockets in Si_3N_4 soften, but the ceramic skeleton remains elastic. As a consequence, the exponential background in Si_3N_4 (**Fig. 15**) is lower than in zirconia (**Fig. 9**), and the creep resistance of this ceramic is higher.

Mechanical Loss and Toughness

An exponential increase in mechanical loss at high temperature means a low creep resistance of the material, because the anelastic or microplastic strain has no limit. On the other hand, damping mechanisms are positive factors for improving toughness in hard and brittle materials. Since a mechanical loss peak is associated with a limited motion of structural defects, it cannot be associated with the onset of creep. It accounts for the ability of the material to dissipate locally a part of the vibration energy and hence to improve toughness by crack propagation blunting.

As an example, **Fig. 19(a)** shows the mechanical loss spectra of two grades of zircon (ZrSiO_4) (Carbonneau, 1997) differing by the content of the inter-granular glassy phase. **Fig. 19(b)** shows that a K_{Ic} maximum is observed only in the grade that exhibits a mechanical loss peak.

Since the mechanical loss accounts for energy dissipation in the solid, one can try to link it with the strain energy release rate G_{Ic} (Schaller and Fantozzi, 2001):

$$G_{Ic} = - \frac{dU}{h \cdot da} \quad (19)$$

where dU represents the potential energy release when the crack grows of “ da ”, the specimen thickness being of “ h ”. In brittle materials, an increase in the potential energy release ΔG_{Ic} can be due to an increase in the energy dissipation ΔW_{diss} in a volume V in front of the crack tip. When ΔW_{diss} is due to an internal friction mechanism, the eqs. (9) and (12) can be used for calculating ΔW_{diss} . Then:

$$\Delta G_{Ic} = -\frac{\Delta(dU)}{h \cdot da} = \frac{V \cdot \Delta W_{diss}}{h \cdot da} = \frac{2\pi \cdot V \cdot W_{el}}{h \cdot da} \cdot \Delta \tan(\phi) \quad (20)$$

where W_{el} is the maximum stored elastic energy per unit volume and $\Delta \tan \phi$ the increase in damping, respectively.

Supposing that the volume V is a cylinder of radius r and height h , which is translated of da when crack propagates, the increase ΔG_{Ic} of the strain energy release rate G is:

$$\Delta G_{Ic} = 4\pi \cdot r \cdot W_{el} \cdot \Delta \tan(\phi) \quad (21)$$

Taking into account the height of the mechanical loss peak $\Delta \tan(\phi)$ (Fig. 19(a)), and considering that crack propagation in zircon is enhanced under an applied stress of 200 MPa, one obtains $\Delta G_{Ic} = \sim 7\text{--}70 \text{ Jm}^{-2}$ depending on the value of the zone radius $r = \sim 0.1\text{--}1 \text{ mm}$ respectively. On the other hand, in the case of elastic materials, it is possible to derive ΔG_{Ic} from the increase in K_{Ic} associated with the toughness peak. One obtains $\Delta G_{Ic} = 32 \text{ Jm}^{-2}$, value of the same order of magnitude as the one predicted from mechanical loss peak. In fact, it is not evident to get a quantitative value of ΔG_{Ic} from the mechanical spectroscopy because of the estimation of the radius r of the dissipative zone, which has to be larger than the plastic zone considered in the models of fracture mechanics. However, from a qualitative point of view, it is clear that a mechanical loss peak is beneficial for toughness. For instance, it has been shown that the ability of Si_3N_4 to dissipate energy in the glassy phase decreases the strain accumulation under cyclic loading and consequently improves fatigue resistance (Roebben *et al.*, 1998).

Conclusions

Ceramics are generally considered as brittle materials. However, at relatively high temperatures, plastic yield can be observed defining a brittle-to-ductile transition. Such a transition, is often marked by a mechanical loss peak, which evolves into an exponential background at higher temperature. From the viewpoint of mechanical spectroscopy, the brittle-to-ductile transition can be decomposed into two stages: a brittle-to-“tough” transition associated with the relaxation peak and a “tough”-to-ductile transition associated with the exponential background. Structural ceramics have to be tough and creep resistant. In other words, they have to exhibit a mechanical loss peak with a low level of the high temperature background.

In the case of Si_3N_4 , it was shown that the mechanical loss peak was due to the α -relaxation in the pockets of YSiAlON type glass (Donzel *et al.*, 1997). Crystallization of these glassy pockets by thermal treatments led to an improved creep resistance (Besson *et al.*, 1998). Fine-grained zirconia presents a mechanical loss peak, which is not well resolved with respect to the exponential background. In these ceramics, the regular shape of the grains does not provide a strong restoring force in the GB sliding process and therefore extended creep can be observed. GB sliding is lubricated by amorphous intergranular films and anelastic relaxation is affected by the glass transition in these films. As these films are very stable, one way to limit GB sliding is to introduce hard particles or whiskers, for instance of SiC type or carbon nanotubes, at the triple points.

To conclude, the brittle-to-ductile transition in hard materials like ceramics or ceramic composites can be studied by mechanical spectroscopy. An appropriate strategy is to compare carefully the damping spectrum with the mechanical behavior determined by other techniques (creep tests, toughness tests). Moreover, transmission electron microscopy observations are of particular interest in modeling the damping mechanisms. Damping is important for toughness and for fatigue resistance of ceramics (Roebben *et al.*, 1996).

Indentation of Ceramics

Emilio Jiménez-Piqué, Universitat Politècnica de Catalunya-Barcelona TECH & Barcelona Research Center in Multiscale Science and Engineering, Barcelona, Spain

Introduction

One of the outstanding properties of ceramics is their high hardness, that is, they are resistant to permanent deformation produced by contact loads. Due to this property, there are many engineering applications where ceramics have a competitive advantage over metals. In fact, wear resistance and scratch resistance are a consequence of the high hardness and stiffness of ceramics, which translate in higher durability and performance. Therefore, applications such as ceramic bearings, cutting tools, grinding, motor components, or biomedical prosthesis require benefit from the high hardness of ceramics.

In addition, measuring hardness is a versatile and straightforward technique to assess mechanical properties of ceramics at local level. Hardness imprints are generated by inelastic mechanisms, which can be dislocation movement, twinning, phase transitions, densification or microcracking, depending on the material. Therefore, insights on these deformation mechanisms can be acquired by a simple hardness test, instead of a more complex, difficult to perform, mechanical tests. Moreover, hardness tests can be also probe other mechanical properties as well as plasticity: elasticity, fracture toughness, fatigue resistance, creep or impact, among others.

This chapter has the following structure. First, the hardness test using Vickers indenters is described. Then, a short review of the spherical indentation tests is presented. The third part introduces the nanoindentation test, on how it is used to measure hardness and Young's modulus, and the special precautions to be taken in case of testing ceramic materials. Further information is given on testing coatings, particles or grains, as well as porous ceramics and degraded surfaces. The last part covers the measurement of fracture toughness by indentation, the main formulas used, and the possible shortcomings of the technique.

Hardness Tests

Hardness is defined as the permanent deformation produced after indenting with a tip. Hardness tests were first developed as a fast and easy quality control test in the metal industry. For example, the name Vickers comes from the company Vickers Ltd, where it was first developed. As a consequence, there are many different hardness tests, based on the geometry of the indenter tip and the way load and/or penetration is measured. Most used ones are Brinell, Rockwell, Knoop and Vickers tests. All these tests, because of their industrial nature, use their own scales and have validity load ranges. It should also be mentioned that the Mohs scale from 1 to 10 using a series of benchmark minerals and putting the mineral in the scale on its ability to scrape the lower ranked minerals, is rarely used in scientific research, although it is the best known to the general public. This scale is more a qualitative test for scratch resistance, and, although being very intuitive, it does not provide consistent quantitative data. Because of the high hardness of ceramics, the main hardness test used in ceramics is by using Vickers indenters, and, in a minor extend, Knoop indenters. Berkovich indenters, which are similar to Vickers, are used in nanoindentation, as discussed later. The reason is because Vickers tests use sharp pyramidal tips, and, hence, produce inelastic deformation even at low loads and a measure can be done even at small loads.

In Vickers test, a four-side pyramidal diamond tip (68° angle) is pressed against a material with a known force P . After indentation, the diagonals of the imprint, d , are measured. Assuming perfect tip geometry, the area of contact (A_c) and the diagonal lengths can be related with

$$A_c = \frac{d^2}{2\sin(136^\circ/2)} \quad (1)$$

and, hence, the Vickers hardness is measured as:

$$H_V = \frac{P}{A_c} = 1.8544 \frac{P}{d^2} \quad (2)$$

In Vickers test, the load is measured in kgf and the diagonals in mm, and, consequently, units are, when reported, kgf/mm², or just in "Vickers number". A straightforward conversion into MPa can be done by multiplying the hardness value by 9.8 m/s². However, it has to be considered that Vickers hardness uses projected area, and therefore cannot be directly converted into a plastic stress. A more fundamental definition of hardness is Meyer's hardness that uses projected area instead with the same experimental setup. Discrepancies of 10% of hardness are then expected between both hardness tests. Meyer's hardness is used in instrumented indentation, and will be described with more detail later.

Values of hardness for ceramics vary between a few GPa for ionic bonded ceramics to even 50 GPa in case of boron nitride (Vepřek, 1999) or 100 GPa for diamond, the hardest material known, with typical values of advanced ceramics of 20 GPa for alumina, 23 GPa for SiC or 12 GPa for zirconia (Gallo *et al.*, 2019; Holleck, 1986). All these values have to be considered as

approximate, as the exact values depend strongly on the particular microstructure and, naturally, the processing route followed to produce the particular material to be tested (Rice *et al.*, 1994).

Spherical Contact

While sharp indentations are used to assess hardness because they produce inelastic deformation from the first moment of contact, indentations produced by blunt indenters produce an initial elastic contact which develops into elasto-plasticity at larger loads. This permits to study elastic regimes of the material as well as onset on inelastic deformation mechanisms, such as dislocation movement, micro-cracking or twinning. In addition, this type of contact is similar to the ones typically suffered during in-service conditions, where most contact loads are blunt in nature. The most used blunt indenters are spherical ones because it is easy to obtain spherical indenters (e.g., using bearing balls), the radius of curvature is known and there are no uncertainties in the first initial point with the ceramic. Consequently, we will only refer to spherical indenters for the rest of the chapter.

Spherical indentations are not self-similar, meaning that stresses will change upon load. This provide a methodology to activate different deformation mechanisms with different loads in a single test. At very low loads, the stress will be low and the contact will be elastic. Upon increasing loads, higher stresses will be generated underneath the indenter that will result in inelastic deformation, mainly by the shear stresses produced underneath the indenter. In addition, hoop stresses are produced around the indentation imprint, which can produce a crack in the material, even in full elastic regime. Therefore, spherical contact can produce damage in materials by generating inelastic deformation or by generating a crack in elastic regime.

Equations determining the stresses as a function of load were developed by Hertz in 1886 (Hertz, 1878). These equations shown that, when a sphere of radius R is pressed against a flat solid, the relationship between the contact radius (a) and the load (P) for small penetration depths equals to:

$$a^3 = \frac{3PR}{4E_{eff}} \quad (3)$$

where E_{eff} is the effective modulus between the sample and the indenter, which is defined as:

$$\frac{1}{E_{eff}} = \frac{1 - \nu^2}{E} + \frac{1 - \nu_i^2}{E_i} \quad (4)$$

with the subscript i indicating the indenter material (for example, $E_i = 1140$ GPa and $\nu_i = 0.07$ for diamond, $E_i = 380$ GPa and $\nu_i = 0.28$ for alumina and $E_i = 450$ – 700 GPa and $\nu_i = 0.21$ – 0.24 for hard metal).

If the tested material has a radius of curvature (R_m), then instead of using the radius of the indentation sphere in the equations, the effective radius of curvature (R') has to be used:

$$\frac{1}{R'} = \frac{1}{R_m} + \frac{1}{R} \quad (5)$$

The mean pressure between the indenter and the material (p_0) is:

$$p_0 = \frac{P}{\pi a^2} = \frac{4E_{eff}}{3\pi} \left(\frac{a}{R} \right) \quad (6)$$

In the case of spherical indentation, by plotting p_0 against a/R , it is possible to display the stress-strain contact relationship. These types of curves are very useful to study the elastic range and the onset of inelastic deformation. However, they have to be treated with care when analysing the plastic region, as it cannot be directly compared with a uniaxial test.

The maximum tensile stress (σ_{tm}) is produced along the contact perimeter of the contact, and equals to:

$$\sigma_{tm} = \frac{1}{2}(1 - 2\nu)p_0 \quad (7)$$

The maximum shear stress (τ_m) is produced beneath the indentation axis at a depth close to $0.5a$, and equals to:

$$\tau_m = 0.46p_0 \quad (8)$$

In most materials, and according to the Tresca criterion, when the value of τ_m reaches a certain limit ($\tau_m = \sigma_y/2$ where σ_y is the yield strength of the material), the material will start to plastically flow and create a permanent deformation, making a transition from an elastic response to an elasto-plastic response. In hard ceramics, instead of plasticity, quasi-plastic damage can be produced.

If the contact is done at small scale, it is possible to activate dislocations at room temperate. Note that, because there are high hydrostatic stresses underneath the indenter, cracking may be hindered and the yield stress can be reached, activating the dislocation movement (Bull *et al.*, 2016; Gaillard *et al.*, 2006a,b; Page *et al.*, 1992; Tromas *et al.*, 2006). However, hard ceramics have high yield stress, and other inelastic deformation mechanisms may be activated before dislocation movement or twin formation are active.

Eqs. (8) and (9) summarize a competition between two stress components which will produce two different types of damage. One stress is tensile at the surface (Eq. 8), and the other is shear beneath the surface (Eq. 9). On the one hand, tensile stresses around the contact area will trigger grow of surface flaws around the indentation to produce a shallow ring crack which will then

Fig. 1 (a) Typical load-unload curve of an indentation test. (b) Scheme of the indenter contact parameters and the residual imprint.

develop into a cone crack inside the material which will eventually arrest. Note that this is an extremely easy way of introducing a crack in a ceramic material without introducing further damage, which can be useful for studies of structural integrity.

On the other hand, quasi-plastic damage is produced by shear stresses underneath the surface at a depth around $0.5a$. This damage consists in microcracking of the material which will produce an inelastic deformation of the material, and a visible imprint in the surface (Lawn *et al.*, 1994).

These two types of damage are essentially controlled by the geometry of the indenter and the mechanical properties of the material. Indenting with a sphere of small radii will tend to produce quasi-plastic damage or plasticity, while spheres with large radii tend to produce cone cracking. Hard and brittle ceramics are more prone to cone cracking, while more ductile and tough ceramics will suffer quasi-plastic damage before cone cracking.

Therefore, ceramics as glass or porcelain will produce cone cracking, and tough ceramics as zirconia or ceramic composites will quasi-plastically deform. Ceramics such as SiC, Al_2O_3 or Si_3N_4 may present one type of damage or the other depending on the microstructure (particularly the grain size) and the type of indenter used.

Further information on the topic can be found in a devoted article of spherical contact of hard materials in the Comprehensive Hard Materials (Jiménez-Pique *et al.*, 2014a,b) as well as in several excellent reviews in the literature (Basu *et al.*, 2006; Fischer-Cripps and Collins, 1994; Ghaednia *et al.*, 2017; Lawn, 1998; Pathak and Kalidindi, 2015).

Nanoindentation

Instrumented indentation is similar to a hardness test, with the difference that the load and the displacement into the surface of the indenter are continuously measured during both loading and unloading parts of the test. Because of the high spatial resolutions achievable with most experimental equipment, the technique is also known as nanoindentation.

Nanoindentation is now a widespread technique to measure hardness and Young's modulus of materials. However, because of the small volumes probed, it is especially suited to probe coatings, surfaces or small microstructural features as grains, second phases, interfaces or damage surfaces. In addition, using other tips or loading methods, it allows measuring other relevant mechanical properties, as yield strength, creep, friction and, specially, fracturing toughness. Therefore, the technique is extremely versatile and provides a unique toolbox for probing microstructures of ceramics at extremely low scale.

Based on the analysis of the load (P)-displacement (h) curves it is possible to calculate the mechanical properties of the material. Fig. 1 presents an example of a P - h curve as well as the most relevant geometrical parameters used in the next section. The most used analysis used to extract both hardness and Young's modulus of the material is the one based on the work of Oliver and Pharr (1992), which it will be briefly reviewed here. The reader is referred to more extensive review papers in references (Fischer-Cripps, 2006, 2000; Golovin, 2008; Gouldstone *et al.*, 2007; Oliver and Pharr, 2010, 2004; Pharr, 1998; VanLandingham, 2003).

The Oliver and Pharr Method

The Oliver and Pharr method is now extensively used to measure Young's modulus and hardness of a variety of materials, and it is similar to the standard for instrumented indentation ISO 14577. The method is based on calculating the elastic unloading stiffness after fitting the unloading curve with a power law relation:

$$P = \alpha(h - h_f)^m \quad (9)$$

With α and m fitting parameters, and h_f the final depth. Stiffness is calculated as:

$$S = \left. \frac{dP}{dh} \right|_{h_{max}} \quad (10)$$

Fig. 2 Scheme of the most common sharp indentation tips, together with their most relevant geometrical parameters.

It has to be said that for hard materials, as ceramics, stiffness can also be estimated as the slope of the first points of the unloading curve without the necessity of adjusting the loading curve with the power law relationship. If stiffness is known, the contact depth (h_c) between the indenter and the sample at maximum load (P_{max} , h_{max}) can be calculated as:

$$h_c = h_{max} - \varepsilon \frac{P_{max}}{S} \quad (11)$$

Once the contact depth is known, the contact area $A(h_c)$ can be calculated. Note the dependency with h_c , as it is not a universal or constant value. This area will depend on the geometry of the indenter used. In nanoindentation testing, the most used indentation tip is a three-side Berkovich indenter, with its relationship between base and area similar to a Vickers tip. Reason for this is because all three-side pyramids end in a single point, while four-side pyramids may end in a vertex if they are not perfectly manufactured (they are not at nanometric level). **Fig. 2** presents a scheme of the most used tips. It has to be considered that tips, specially at low scales, are not perfect and the particular relationship between area and contact depth, $A(h_c)$, should be calibrated against a material with well-known properties (usually fused silica). The function will depend on the particular tip used as manufacturing of tips is not perfect, and will change as the indenter tip is worn with use. Once $A(h_c)$ is known, the hardness and Young's modulus are calculated as:

$$H = \frac{P_{max}}{A(h_c)} \quad (12)$$

and:

$$E_{eff} = \frac{\sqrt{\pi}}{2\beta} \frac{S}{\sqrt{A(h_c)}} \quad (13)$$

Being β a correction factor (usually 1.034) and E_{eff} defined in [Eq. \(4\)](#).

While this method extracts E and H at maximum applied load, acquiring single couple of values per test, it is possible to introduce small unloading cycles in the loading part. By measuring stiffness in the loading part, it is possible to measure H and E as the indenter penetrates the material. The exact way to do this depends on the particular nanoindentation instrument, and usually is different between instruments. This technique is of special interest when material properties change with penetration depth, as in case of coatings, particles or modified surfaces, however, it can be also used to understand elasto-plastic transitions at small scale.

In **Fig. 3**, a nanoindentation test on a single grain of a 3Y-TZP ceramic is presented. The P - h curve is presented, as well as the continuous measurement of both E and H with the continuous stiffness measurement technique. Observe as well that at small penetration depths ($h \approx 60$ nm), the tip is blunt and the contact behavior can be modeled as spherical Hertzian contact (dotted line). The departure from a perfectly sharp tip produces a decrease of apparent Young's modulus and hardness. The maximum in hardness corresponds to the maximum contact stress to generate deformation.

Nanoindentation of Ceramics

Regarding the particular case of ceramics testing by nanoindentation, there are some precautions to be taken. First of all, most advanced ceramics do have a large Young's modulus. This results in a stiff contact and, at sufficient high loads, this contact stiffness will be comparable to the frame stiffness of the testing machine, resulting in a convolution of both stiffness. This may yield erroneous values of both hardness and Young's modulus. While this problem is seldom noticed for compliant materials, it can be relevant for technical hard ceramics even at low loads. For example, nanoindentations in cubic boron nitride at depths as low as 1000 nm produce a contact stiffness in the order of magnitude of 10^6 N/m. Therefore, the frame stiffness of the machine has to be deconvoluted from the results, by measuring it against a material with well know properties (e.g., W single crystals) and subtracting it from the measured stiffness. It is important to use a different material for frame stiffness calibration than for tip shape calibration, as otherwise the measures will interfere with each other.

Another factor to be considered is the exact value of the correction factor β . This correction factor was introduced to account for the lack of axisymmetry of the Berkovich indenters, as well as the large lateral strains induced. In the original paper of [Oliver and](#)

Fig. 3 Nanoindentation of a single grain of zirconia. Load displacement curves as well as hardness and Young's modulus obtained by continuous stiffness measurement are presented. Transition from Hertzian contact due to tip rounding occurs at around 60 nm. Reproduced with permission from Gaillard, Y., Anglada, M., Jimenez-Pique, E., 2009. Nanoindentation of yttria-doped zirconia: Effect of crystallographic structure on deformation mechanisms. *J. Mater. Res.* 24, 719–727. doi:10.1557/JMR.2009.0091.

Pharr (1992), the value of β was 1.034, and it is still a largely used quantity. However, there is still an open debate on the value of this correction, with proposed values ranging between 1 and approximately 1.3 (Cao *et al.*, 2007; Hay *et al.*, 1999; Larsson *et al.*, 1996; Xu and Li, 2008). Evenmore, this correction factor may not be universal, but dependent on the Poisson ratio of the indented material. For example Larsson *et al.* (1996) propose the following correction for the correction factor β :

$$\beta = 1.2304 \cdot (1 - 0.21\nu - 0.01\nu^2 - 0.41\nu^3) \quad (14)$$

Note that the value of the correction factor has an immediate consequence on the value of Young's modulus, and may yield higher values of Young's modulus than expected. For example, typical values of Young's modulus reported in the literature for zirconia ceramics (3Y-TZP) are around 240 GPa using the correction value of 1.034 (Cattani-Lorente *et al.*, 2016; Gaillard *et al.*, 2009; Rayón *et al.*, 2013). Use of a correction factor of 1.122 will yield values of 220 GPa instead, closer to the ones reported by other techniques.

Contact area in ceramic materials is normally well estimated with no pile up typical of softer materials as metals or polymers, but it is a good practice to observe the indentation imprints, specially to observe if microcracking, phase transformation, decohesion or other non-plastic events have taken place, which will, of course, produce inaccurate values of the mechanical properties.

As a final point, it is important to perform the measurements in a well-polished surface. If the tested surface is rough, this will result in a large scattering in the measured values and accordingly an uncertainty in the measured values. For ceramics, standard polishing with diamond paste until mirror finish should suffice for most measurements, without the need for extreme flatness required in other techniques (e.g., atomic force microscopy or EBSD).

Measuring the Intrinsic Properties of Coatings

Ceramic coatings are widely used in many industrial applications because of their wear resistance, chemical resistance and thermal properties. Applications range from hard coatings in the tool industry, to biomedical coatings or thermal protections. Because of the small thickness of the coatings, the best tool to measure the mechanical properties is by nanoindentation. However, and especially if the coating is thin, the measure can be a convolution of both the mechanical properties of the coating and the substrate. Deconvoluting the substrate-coating response is, therefore a requirement to properly measure the ceramic coatings.

The measurement of hardness is confined to the region of the plastic deformation. Although this volume varies for different materials; for ceramics, it is usually less than ten times the penetration depth, a little bit larger than the size of the diagonal of the indentation imprint, as a rule of thumb. Due to this, it is generally accepted that, if the penetration depth of the indentation is less than one tenth the thickness of the coating, the measured hardness is the true hardness of the coating. This is known as the "10% rule".

Fig. 4 presents cross-sections of a DLC coating on a hard metal. This coating was around 2000 nm thick. When an indentation was done up to 1000 nm maximum penetration depth, the substrate was also deformed and, consequently, the measured hardness was a combination of both substrate and coating. If the indentation was done until 100 nm maximum penetration depth, all deformation was constrained in the coating and the measured hardness value was the true coating hardness value.

Fig. 4 Nanoindentations on a DLC coating on a cemented carbide. (a) When indenting up to 1000 nm maximum depth, both coating and substrate deform plastically. (b) At 100 nm maximum penetration depth, all plastic deformation is confined in the material. The residual imprint is indicated with an arrow.

If it is not possible to apply the 10% rule, there are several models to deconvolute the combined response of the experimental measurements in order to extract the hardness of the coating, assuming that the thickness of the coating is known as well as the mechanical properties of the substrate, adjusting through analytical formulas (Bhattacharya and Nix, 1991; Chicot and Lesage, 1995; Jönsson and Hogmark, 1984) or parametric adjustments (Korsunsky *et al.*, 1998; Puchi-Cabrera *et al.*, 2002).

In case of Young's modulus, the problem is similar, but with the difference that elastic fields are broader than plastic fields. This implies that when the material is indented a much larger volume of material is probed. As a consequence, the "10% rule" cannot be applied. That is, even if the penetration depth of the indentation is less than 10% of the coating thickness, the measured Young's modulus will be also affected by the elastic properties of the substrate. Only very shallow indentations (in the order of 1% of the coating thickness) are able to probe with reliability of the Young's modulus of the coating without the influence of the substrate. These shallow indentations are not easy to perform, and extremely sharp tips should be used to avoid tip rounding effects.

In this case, the use of models to extract the Young's modulus of the coating is recommended. There are several methods proposed in the literature (Bec *et al.*, 2006; Hay and Crawford, 2011; Jäger, 2002; Rar *et al.*, 2002; Saha and Nix, 2002), but most of them yield similar results if no large penetration depths are used and the differences in mechanical properties between coating and substrate are not extreme. Most of them are valid only for indentation depth below the coating thickness. In this sense, Fig. 5 presents the adjustment by different models of a nanoindentation of a 500 nm thick mullite coating on SiC (Botero *et al.*, 2012b). It can be seen how the produced results of the different models are similar, if the indentation is confined inside the coating. Once the indentation reaches the interface with the substrate, models diverge and fail.

Therefore, although use of various models to analyze experimental data is advised to generate robust results, use of a single model can yield good results. Even, in some cases, if the data comes from a continuous stiffness measurement and Young's modulus is measured continuously with penetration, a good estimation of the Young's modulus of the coating can be made just by extrapolating the measure of Young's modulus to zero penetration depth, as proposed in ISO 14577.

Measuring Single Grains

Measuring the mechanical properties of single grains or particles is especially relevant in ceramic composites such as alumina-zirconia, cermets or CBN composites, among others. In this case, the way to proceed to isolate the mechanical properties of a single particle is similar to the way coatings are measured, and numerical models may be used.

However, there are more uncertainties inherent to this type of measurement. First of all, the diameter of the indented particle at the surface may be known, but its exact depth is unknown. This depth may be measured by post-mortem cross-sectioning by, e.g., FIB, but it is experimentally cumbersome. Another way to proceed is to indent several particles and apply a thin film model to the average of the mechanical responses and the average of the particle diameter.

Another approach to follow, if one of the phases has known properties, is to perform a larger amount of nanoindentations at random. As the response will be a contribution of both phases, applying a rule of mixtures (Reuss and Voigt) will give upper and lower values of the second phases. This approach is similar to the massive nanoindentation approach described latter.

When applying thin film models in this context, it has to be taken into account that the elasto plastic properties will be affected by the whole matrix surrounding it. That is, not only the material below the particle may affect the response, as in the case of coatings, but also the surrounding material may have an effect, albeit small, in the mechanical response. In this case, a modified thin film model may be used to take this contribution explicitly into account, as the one proposed by (Botero *et al.*, 2012a) after the model of (Hay and Crawford, 2011).

Statistical Nanoindentation

Modern nanoindentation instruments have increased dramatically the speed of indentations, with current commercial instruments performing a single indent as fast as one per second. Previous generation of machines had speeds in the order of one indentation

Fig. 5 Nanoindentation of a mullite coating on SiC. The coating thickness is indicated with a dotted line. The experimental data show an apparent Young's modulus that increase with depth, result of the convolution of the response of both the coating and substrate. Models proposed by (Bec *et al.*; Hay and Crawford; Rar *et al.*; Saha and Nix), are used to extract the Young's modulus of mullite ($E = 100$ GPa). Models produce similar results, but diverge when using data obtained for larger penetration depths than the coating thickness. Proposed by Bec, S., Tonck, A., Loubet, J.L., 2006. A simple guide to determine elastic properties of films on substrate from nanoindentation experiments. *Philos. Mag.* 86, 5347–5358. doi:10.1080/14786430600660856. Hay, J., Crawford, B., 2011. Measuring substrate-independent modulus of thin films. *J. Mater. Res.* 26, 727–738. doi:10.1557/jmr.2011.8. Rar, A., Song, H., Pharr, G.M., 2002. Assessment of new relation for the elastic compliance of a film-substrate system. *MRS Online Proc. Libr.* 695, 431–436. Saha, R., Nix, W.D., 2002. Effects of the substrate on the determination of thin film mechanical properties by nanoindentation. *Acta Mater.* 50 (1), 23–38. Reproduced with permission from Botero, C.A., Jiménez-Piqué, E., Seuba, J., *et al.*, 2012b. Mechanical behavior of $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ films under nanoindentation. *Acta Mater.* 60, 5889–5899. doi:10.1016/j.actamat.2012.07.031.

per ten minutes. This high speed allows to produce a large amount of indentations in a reasonable amount of time, with the advantage of allowing for a statistical interpretation of the results obtained, especially when different phases exist in the material, as well as the possibility to generate property maps of a surface (Tromas *et al.*, 2010). This eliminates the necessity of selecting the phase of interest and the potentially laborious procedure as outlined before.

While there is many statistical techniques available, one of the most used ones is the method applied by Constantinides *et al.* (2003), Ulm *et al.* (2007). This method is based on assuming that the existing phases follow a Gaussian distribution of the values of hardness and Young's modulus. The method is relatively easy to perform, although it assumes that the scattering in properties is purely Gaussian.

As an example, Fig. 6 presents the results of statistical massive nanoindentation on a WC – cobalt hard metal (Roa *et al.*, 2015). It is seen how the technique is able to discern, not only between the metallic phase and the ceramic grains, but also on the differences on hardness on the prismatic and basal crystal orientations.

Porosity

Porosity is an important feature in ceramics, being this porosity made on purpose or as a consequence of processing. Even small amounts of porosity can influence the mechanical response under indentation. Understanding the effect of the porosity in this response is important not only to correct the results but also as a tool to quantify the amount of porosity in the material.

There are several formulas in the literature to account for the reduction of mechanical properties with porosity. For small amounts of porosity even a linear relationship is sometimes used, however it is more common to relate the change in properties with an exponential law. In case of Young's modulus, this reads as (He *et al.*, 2008; Amorós *et al.*, 2020):

$$E = E_0 \exp(-\gamma P) \quad (15)$$

Where E_0 is the elastic modulus of a pore-free material, P is the pore volume fraction and γ is an adjustment parameter.

If pores are not spherical, the formula proposed by Luo and Stevens can be used (Chintapalli *et al.*, 2012; Luo and Stevens, 1999, 1996):

$$E = E_0 \frac{1 - P}{1 + \alpha P} \quad (16)$$

Where α is a parameter that depends on the shape of the pores. This parameter is $\alpha = 1$ in case of spherical pores.

This model assume an elastic behavior of the pores, that is, the material does not collapse under indentation, and the shape of the pores remains the same after the test. Of course, for materials that are brittle or have a high amount of porosity this does not happen. In this case, more complex analysis have to be performed to deconvolute the effect of the porosity (Chen *et al.*, 2006; Ko *et al.*, 2006).

Fig. 6 Statistical nanoindentation on a WC-Co hard metal. A matrix of indentations is made and the data is latter treated to extract the mechanical properties of both orientations of WC gains as well as the cobalt phase. Reproduced with permission from Roa, J.J., Jimenez-Pique, E., Verge, C., *et al.*, 2015. Intrinsic hardness of constitutive phases in WC-Co composites: Nanoindentation testing, statistical analysis, WC crystal orientation effects and flow stress for the constrained metallic binder. *J. Eur. Ceram. Soc.* 35, 3419–3425. doi:10.1016/j.jeurceramsoc.2015.04.021.

Weak Interfaces

The same reasoning is applied to materials that have weak interfaces. This is specially the case of ceramic coatings with columnar structures, typical of PVD or CVD process, for example thermal barrier coatings for gas turbines. In this case, relative sliding between columns will result in an immediate drop in mechanical properties at shallow penetration depths (much earlier than reaching the 10% of the penetration depth) (Botero *et al.*, 2012a,b; Gaillard *et al.*, 2007, 2006a,b). This can be seen in Fig. 7 where the nanoindentation of top of an 8%Y₂O₃-ZrO₂ thermal barrier coating produced by EB-PVD and APS is presented. EB-PVD produces a columnar microstructure, while APS produces a splat-like microstructure. The coating is 200 μm thick, but elastic modulus decreases sharply even in the first stages of contact loading. For large penetration depths, the asymptotic value of *E* is 100 GPa. However, the Young's modulus of zirconia measured by nanoindentation is 240 GPa, which lowers to 190 GPa once the microporosity is taken into account. The sharp decrease of Young's modulus is then attributed to the weak interfaces between columns (EB-PVD) and splats (APS) that result in partial displacement between microstructural features.

A similar effect can be seen in Fig. 8, where Young's modulus vs. penetration depth of a columnar TiO₂ coating on silicon substrate is presented. In this case different glancing angles are used to produce slanted columns. Although column size and density were similar for the three angles presented, the incidence angle had a clear influence in the measured value.

Therefore, it is important to consider the possible weak interfaces in the material, as they will largely impact in the mechanical response. Understanding the precise deformation mechanisms is not trivial, and depends strongly on the type of material and the nature of the weak interfaces. Hence, it is usually necessary to perform further in-depth studies by microscopy techniques.

Degraded Surfaces

Upon service, materials may be subjected to degradation by many causes, including wear, corrosion, radiation or environment interactions. This mainly affects the surface of the material, changing its chemical composition, its crystallography, its plasticity or generating microcracking. This degraded surface has different mechanical properties of the rest of the bulk, and can have detrimental effects on the structural integrity and reliability of the material under service. Because it is generally well confined in the first microns of the surface, nanoindentation is especially suited to measure this degraded layer.

The approach generally used is to consider the degraded layer as a coating with different properties as the bulk material, and then applying the techniques and considerations described before for coatings (Afrasiabi and Kobayashi, 2013; Zheng *et al.*, 2019). However, it has to be taken into account that roughness may have increased during the degradation process and polishing may be necessary to produce data with higher reliability.

Fig. 9 presents the result of nanoindentation performed on zirconia (3Y-TZP) subjected to low temperature degradation (Botero *et al.*, 2015; Gaillard *et al.*, 2008; Muñoz-Tabares *et al.*, 2011a). During this degradation, the metastable tetragonal phase reverts to monoclinic phase, producing microcracking due to the slightly higher volume of the monoclinic phase. By indentation it is possible to measure the properties of the degraded layer as well as the thickness of the degradation surface as a function of the degradation time just by considering the degraded layer as a coating. Measuring the degradation by this technique has the advantage of probing a small volume, so spatial resolution is higher than other spectroscopic techniques.

Fig. 7 Evolution of the Young's modulus as a function of the penetration depth of the indenter for APS and EB-PVD thermal barrier coatings. Weak interfaces in the microstructure produce a significant decrease in Young's modulus even at low penetration depths (below 1% of the coating thickness).

Fig. 8 Young's modulus of TiO_2 coating. While composition and density is similar, the different orientation of the columns produce a significant difference in the nanoindentation measurement. Reproduced with permission from Jiménez-Piqué, E., González-García, L., Rico, V.J., González-Elípe, A.R., 2014b. Nanoindentation of nanocolumnar TiO_2 thin films with single and stacked zig-zag layers. *Thin Solid Films* 550, 444–449. doi:10.1016/j.tsf.2013.10.022.

Fracture Toughness by Indentation

Indentation can also be used to estimate the fracture toughness of ceramics. Because of the high hardness of ceramics, upon application of load, the strain energy accumulated by the inelastic deformation can be released by fracture. This opens the door to measure fracture toughness in an easy way, without much sample preparation and in a local level (Lawn and Wilshaw, 1975; Leonardi *et al.*, 2009; Morrell, 2006; Ostojic and McPherson, 1987).

The method is based in measuring the lengths of the cracks produced at the vertex of the indentations at a given load. Vickers indenters are normally used at 50 kg load. Cube corner indenters are used in nanoindentation tests at smaller loads. Other indenters (e.g., Knoop) can also be used as well. Fig. 10 presents an image of cracks produced in different materials by cube corner nanoindentation.

Fig. 9 (a) Nanoindentation of a low temperature degraded zirconia, up to 72 h in autoclave. Observe how the mechanical response diminish with degradation time. (b) By adjusting a thin-film model to the nanoindentation response, it is possible to evaluate the depth of the degradation, corroborated by micro-Raman microscopy and cross-section observations. Subsurface evaluation of hydrothermal degradation of zirconia. *Acta Mater.* 59, 473–484. doi:10.1016/j.actamat.2010.09.047.

Fig. 10 Cube corner indentation, at different loads of (a) Soda-lime-glass, (b) Silicon single crystal, (c) Silicon Carbide single crystal (d) a WC grain of a hard metal, (e) YSZ single crystal. Observe how the cracks emanate from the vertex in the case (a) to (c), while deviations from the model occur in (d) and (e). Reproduced with permission from Cuadrado, N., Seuba, J., Casellas, D., Anglada, M., Jiménez-Piqué, E., 2015. Geometry of nanoindentation cube-corner cracks observed by FIB tomography: Implication for fracture resistance estimation. *J. Eur. Ceram. Soc.* 35, 2949–2955. doi:10.1016/j.jeurceramsoc.2015.03.031.

The most used formula to calculate fracture toughness is the one originally proposed by [Anstis et al. \(1981\)](#):

$$K_{Ic} = \xi \left(\frac{E}{H} \right)^{1/2} \frac{P}{c^{3/2}} \quad (17)$$

where E is the Young's modulus, H is the hardness, P is the indentation load and $2c$ is the total crack length (i.e., $c = l + a$, where l is the length of the crack from the indentation corner, and $2a$ is the indentation diagonal) and ξ is a material constant calibrated against materials with well-known fracture toughness, with a generally accepted value of $\xi = 0.016$. See [Fig. 11](#) for a graphical description of the geometric parameters.

Fig. 11 (a) Scheme of a cube corner indentation with cracks. (b) Scheme of a cube corner indentation with cracks. (c) Cross section of an indentation that induces a semielliptical crack (d) Cross section of an indentation that induces a semielliptical crack. Reproduced with permission from Cuadrado, N., Seuba, J., Casellas, D., Anglada, M., Jiménez-Piqué, E., 2015. Geometry of nanoindentation cube-corner cracks observed by FIB tomography: Implication for fracture resistance estimation. *J. Eur. Ceram. Soc.* 35, 2949–2955. doi:10.1016/j.jeurceramsoc.2015.03.031.

The model assumes that the produced cracks are half-penny (semi-circular), and that no other energy dissipation is activated during indentation. In order to fulfill Anstis equation, the cracks have to be far away of the indentation to not be affected by the residual stresses, so the crack length has to be sufficient large to fulfill $c > 3a$.

The mechanism responsible of crack generation is as follows. Upon indentation, an inelastic deformation is generated under the indenter. This deformation is in compression, but induces tensile stresses in the surrounding volume. This tensile stresses ultimately generate a crack from the vertex which grows and ultimately arrest as the residual stresses decrease away from the indentation.

Fig. 12 presents an experimental FIB tomography of this process in soda lime glass. This tomography was done for cube corner indenters under nanoindentation but follows the same mechanisms as Vickers indentations (Cuadrado *et al.*, 2015). In this series of images, it is seen how a crack is produced underneath the indenter and propagates away of the indentation. The crack is alienated with the vertex of the indentation. As the load is increased, the length of these cracks is also increased. Observe as well that the cracks do not grow underneath the indenter, because in this region the residual stresses are compressive and, consequently, the stress intensity factor reverses sign and the crack cannot open. It is also interesting to point out that, although the indentation is performed in a well-behaved material, secondary cracks also appear.

It is important to understand that indentation can produce cracks with very different geometries, depending on the load and the type of material. A review of the shape of the cracks produced by indentation can be found in (Cook and Pharr, 1990).

There are other formulas to evaluate K_{Ic} in case other crack shapes are produced. If Palmqvist cracks are produced (see Fig. 11), the formula proposed by Laugier can be used:

$$K_{Ic} = \chi \left(\frac{l}{a} \right)^{-1/2} \left(\frac{E}{H} \right)^{2/3} \frac{P}{c^{3/2}} \quad (18)$$

Where χ is a material parameter equal to $\chi = 0.015$. However, the equation can be applied only as far as the ratio between crack length and indentation semi-diagonal are in a specific range [26]. The crack length should obey the requirement of $0.25a < l < 2.5a$. This type of Palmqvist cracks are typical of tough ceramics, with values in the order of 4–10 MPa m^{1/2}.

The same methodology can be used for nanoindentation tests. In order to induce cracking at lower loads, that is, in smaller regions of interest, a cube-corner indenter is used instead of Vickers or Berkovich indenters. The reason is that for this more acute tip, the residual stress generated by the deformed material underneath the nanoindentation imprint is larger, and, hence will produce cracking at much lower loads (in the order of mN for most brittle materials).

In case of cube-corner tips, the same formulas can be applied, but the material parameters ξ and χ have to be modified to $\xi = 0.026$ and $\chi = 0.057$, respectively (Cuadrado *et al.*, 2012).

There are several variations of these two equations, mainly on the value of the material parameter constant or the effect of the E/H ratio (Evans and Charles, 1976; Laugier, 1987; Ponton, 1985; Ponton and Rawlings, 1989) or the ellipticity of the cracks produced (Smith and Scattergood, 1992), as well as residual stress (Marshall and Lawn, 1977). In this case, assuming that the cracks are half-penny, the measured fracture toughness is affected by the surface residual stresses, as they will tend to close the crack and make it shorter (if compressive) or open it and, consequently, make it larger (if tensile):

Fig. 12 Tomography of the cracks produced by cube-corner nanoindentations in soda-lime glass. Indentation imprints are colored in yellow, and cracks in magenta. Reproduced with permission from Cuadrado, N., Seuba, J., Casellas, D., Anglada, M., Jiménez-Piqué, E., 2015. Geometry of nanoindentation cube-corner cracks observed by FIB tomography: Implication for fracture resistance estimation. *J. Eur. Ceram. Soc.* 35, 2949–2955. doi:10.1016/j.jeurceramsoc.2015.03.031.

$$K_{Ic} = \xi \left(\frac{E}{H} \right)^{1/2} \frac{P}{c^{3/2}} + \psi \sigma_R \sqrt{c} \quad (19)$$

Where σ_R is the residual stress, and ψ is a geometric factor ($\psi = 1.29$ for a half-penny crack configuration). Observe how this formula provides a tool to measure residual stresses in the material, provided that the fracture toughness of the stress-free material is known (Pavon *et al.*, 2006). Fig. 13 shows an example of measurement of the residual stresses produced by grinding of 3YTZP (Muñoz-Tabares *et al.*, 2011b). In this case, for measuring the residual stress profile in depth, the ground surface was carefully polished away at a controlled depth while performing indentations at each step. As the material was removed, the cracks were becoming larger, indicating that the compressive residual stresses were decreasing with depth. Once the cracks are measured at each step, the residual stress profile can be quantified through formula (Eq.19).

In conclusion, indentation is a very powerful to estimate fracture toughness in ceramics. It is relatively easy to perform, especially compared to other techniques, where a crack of a given length has to be introduced in a sample of the material of

Fig. 13 Vickers indentations on ground zirconia. Residual stresses are calculated after measuring the crack lengths produced at different depths, available after controlled polishing (a–d). Residual stress calculation after formula (19) (e). Reproduced with permission from Muñoz-Tabares, J.A., Jimenez-Pique, E., Reyes-Gasga, J., Anglada, M., 2011b. Microstructural changes in ground 3Y-TZP and their effect on mechanical properties. *Acta Mater.* 59, 6670–6683. doi:10.1016/j.actamat.2011.07.024.

controlled geometry (for example single edge V-notched beams test). In addition, the indentation technique is local, so small volumes of interest can be measured, as grains, or stressed surfaces.

However, this method has received some criticism (Flanders *et al.*, 2003; Marshall *et al.*, 2015; Quinn and Bradt, 2007), as it often fails to provide a reliable value of fracture toughness. First of all, it has to be understood that what is really measuring the method is an indentation micro-fracture resistance of the material, which is translated into fracture toughness through the material parameters ξ and χ and the E/H relationship. Uncertainty in these values result in a not precise values of K_{Ic} .

Second, and most important, these models assume that the produced cracks have controlled geometries. However, not all materials behave that way. Some indentations in ceramic materials produce a variety of secondary cracks or bifurcation of cracks at the vertex of the tips or even spallation.

Third, the model assumes that the materials are isotropic and elasto-plastic. This means that it is not valid for porous ceramics or ceramic with weak interfaces that are able to dissipate energy by sliding. In fact, indenting a porous ceramic will produce little or no cracks at the vertex of the indentation imprint, but this does not imply that the fracture toughness is high (Melk *et al.*, 2015). Even more, indentation in highly transformable ceramics (as ceria-doped ceramics) may result in an overestimation of the real fracture toughness of this type of materials (Reveron *et al.*, 2017).

In conclusion, the method is versatile, easy to perform, and extremely good to probe small regions of the material. However, care has to be taken to be sure that all assumptions are met in order to measure with confidence fracture toughness. But, although an exact value of fracture toughness may not be measured, a good estimation can be provided, which can be extremely useful specially to compare similar materials.

Summary

Indentation is a very versatile, easy to implement and powerful tool to probe the mechanical properties of the surface of the ceramic materials, with local resolution. The use of different shapes of indenters allows testing different behaviors of the material. With instrumented indentation, the resolution and flexibility are further increased. In addition, indentation microfracture, if properly performed, permits the measurement of fracture toughness of ceramics.

Acknowledgments

I would like to thank my colleagues Y. Gaillard, C. Botero, A. Muñoz-Tabares, N. Cuadrado, J. Roa and L. Llanes, for valuable discussions on the indentation technique. Project PGC2018-096855-B-C41 of the Spanish Ministry of Science and Universities is also acknowledged.

Contact Damage Resistance and Tribological Behavior of Ceramic/Carbon Nanostructure Composites

Introduction

The development of ceramic matrix composites (CMCs) looks for improving the structural and/or functional properties of monolithic ceramics by adding fillers of distinct compositions (carbon, oxides, non-oxides...) and dimensions (nano/micro particles, fibers or whiskers, platelets...) to a ceramic matrix (Low, 2006). These CMCs exhibit, among others, great improvements in the fracture toughness or wear resistance, in the case of structural properties, or large increments in the electrical or thermal conductivities, when functional properties are investigated. Within CMCs, continuous carbon fibers reinforced silicon carbide (C/SiC) ceramic composites are one of the most studied due to their excellent properties (high toughness, good thermal shock and wear resistances, low friction...) that allows using them in high temperature advanced applications, for instance, as brake pads and disks in transportation or in thermal protection systems for aerospace vehicles (Krenkel and Berndt, 2005). Since the first C/SiC CMCs were manufactured in the 1980s, other promising carbon-based fillers were synthesized in the following decades, in particular, one-dimensional carbon nanotubes (CNTs), first described by Iijima (1991), and two-dimensional graphene, reported by Novoselov *et al.* (2004), who received the Nobel Prize in Physics in 2010 for their investigations in this carbon allotrope. These carbon nanostructures -nanotubes and graphene, CNs- attracted a great expectation since their discovery due to their outstanding electronic and physicochemical properties (Novoselov *et al.*, 2012; Popov, 2004), which could potentially enhance the performance of ceramics. The main difficulties to manufacture ceramic/CNs composites mainly are the dispersion of CNs into the matrix and the full densification of the CMCs avoiding the damage of the nanostructures at the high temperatures required during the sintering process. After some years of arduous investigations to mature the technology able to overcome these difficulties and develop the CNs composites, CMCs containing CNTs or graphene already led to remarkable improvements in numerous properties of ceramics (Azarniya *et al.*, 2017; Miranzo *et al.*, 2017). In this way, it is remarkable the development of toughened and highly electrical conducting ceramics.

At present, there is an increasing interest to improve the efficiency in industrial processes, minimizing the energy losses, as they are closely linked to economic and ecological issues. According to Holmberg *et al.* (2012), 28% of the fuel energy in passenger cars is employed to mitigate the undesirable friction phenomena occurred in the engine, transmission, and tires. These authors estimate a worldwide fuel savings of 117,000 MJ, economic savings of 174,000 M€, and reductions in CO₂ emissions of 290 MT if the friction losses are reduced by 18%. A similar study done in paper machines (Holmberg *et al.*, 2013), where the energy wasted due to the friction is in the range of 15–25%, concluded that a reduction in the next years of those numbers by 11% will also decisively contribute to minimize the greenhouse gas emissions, substantially saving money and electricity as well. Within this scenery and focused on the transportation field, one of the current approaches to reduce the fuel consumptions and the harmful emissions to the atmosphere is the development of gasoline direct injection (GDI) systems (Buri *et al.*, 2009), a challenging technology that requires high injection pressures -up to 80 MPa- but produces extensive wear of the GDI metallic parts. Therefore, the development of new materials with a better tribological response is of paramount importance and, in this sense, ceramic/CNs composites could have a decisive influence in these applications in the near future.

In this chapter, the friction behavior and wear resistance of oxide and non-oxide CMCs containing CNTs or graphene-based fillers are reviewed, describing the mechanisms that take place and the role played by CNs in the tribological response. The most common CNs fillers employed in bulk ceramic composites are multi-walled carbon nanotubes (MWCNTs), graphene nanoplatelets (GNPs) and graphene oxide sheets (GOs), which are thinner than GNPs but require a further reducing process (chemical or thermal, rGOs) to mostly recover the properties of graphene. Prior to go in depth on the tribological properties of ceramic/CNs composites, their contact damage resistances are also discussed. Despite this mechanical parameter is unusually analyzed when mechanical studies are performed, typically including hardness, fracture toughness, strength, etc., the contact damage resistance tests are relatively simple and fast, and provide important qualitative and preliminary information of the materials about their expected long- and short-crack behavior, machining performance or wear resistance.

It is important to remark that when the properties of different composites and reference materials are compared, their main microstructural characteristics, such as density, matrix grain size, crystalline phases, etc., must be similar; otherwise, it is quite complicate to elucidate the effect of the fillers in any property, as those microstructural parameters strongly affect the structural and functional properties of the materials.

Contact Damage Resistance of Ceramic/CNs Composites

Lawn's (1998) works were pioneering in the study of the contact damage resistance of ceramic materials employing Hertzian contact tests with spherical indenters and, in particular, the use of the bonding-interface technique. This technique easily allows

Fig. 1 (a) Scheme of the bonding interface configuration to observe top and cross-section surfaces at the Hertzian contact indentation. (b) Subsurface damage beneath the contact of SiC/5 vol% rGOs composite showing an array of mode II microcracks, parallel aligned to the tested surface, which come from the debonding of the SiC-rGO interphase. Adapted from Belmonte, M., Miranzo, P., Osendi, M.I., 2018. Contact damage resistant SiC/graphene nanofiller composites. *Journal of the European Ceramic Society* 38, 41–45.

investigating the damage beneath the contact surface. In essence, two polished half-specimens of the same material are glued face-to-face and, then, the top surface is ground and polished. Afterwards, WC indentations are performed at different loads in the bonded interface and, next, the glued specimens are separated by immersing them in acetone. Finally, the indented top surface and the cross-section beneath that surface are optically examined by Nomarski illumination (**Fig. 1(a)**). Distinct contact damage responses are observed depending on the microstructure of the ceramics. In this sense, homogenous monolithic materials with fine microstructures typically exhibit an elastic-brittle behavior where long well-defined Hertzian cone cracks are developed beneath the contact, which reduces the damage resistance. Conversely, heterogeneous materials, with a mixture of fine/equiaxed and large/elongated grains, present a quasi-ductile response, arresting, or at least limiting, the cone crack formation. In addition, the development of a subsurface damage zone with intergranular microcracks at the matrix-boundary phase interfaces is promoted. This behavior has been associated to the enhanced contact damage resistance of the material (Lawn *et al.*, 1994).

Nowadays, there are scarce works devoted to the contact damage resistance of ceramic/CNTs (Gonzalez-Julian *et al.*, 2011; Lee *et al.*, 2013; Wang *et al.*, 2004) and ceramic/graphene (Belmonte *et al.*, 2018; Roman-Manso *et al.*, 2014) composites. In the case of CNTs, Wang *et al.* (2004) reported well-defined cone cracks in the indented Al_2O_3 surface; while the absence of those cracks in the Al_2O_3 /10 vol% CNTs surface was indicative of a high-shear deformable response of the composite due to the presence of the nanotubes at the grain boundaries. As a consequence, the contact damage response enhanced, similarly to the heterogeneous ceramics described by Lawn *et al.* (1994). Comparable behavior was further confirmed by Gonzalez-Julian *et al.* (2011) in Si_3N_4 /5.3. vol% CNTs composites using the bonding interface technique. These authors observed in the cross-section of the CNTs composites shorter cone cracks than in the unfilled ceramics, as well as a quasi-plastic damage zone in which the weak interphase boundaries between Si_3N_4 and CNTs debonded due to a shear faulting process. As result, many mode II microcracks were formed, promoting the redistribution of the stress field under the indenter and limiting the formation of long cracks. This would also be indicative of enhanced fracture toughness and improved flaw tolerance.

In the case of graphene-based composites, Hertzian contact tests have been performed on SiC ceramics. Roman-Manso *et al.* (2014) found that the resistance to cone/ring cracking augmented in SiC materials due to the presence of multilayered graphene at grain boundaries. These graphene stacks, with a total content of ~ 4 vol%, were in situ grown into the ceramic material during its liquid-phase densification process by using the spark plasma sintering technique. Later, a deeper analysis of the short-crack endurance and contact damage resistance of SiC ceramics containing different graphene fillers (GNPs and rGOs) and amounts (up to 20 vol%) was carried out by Belmonte *et al.* (2018). According to these authors, the stress-strain curves obtained from the

indentation load and the radius of the imprints left on the top surface of the specimens showed a progressive deviation from the elastic-brittle response as GNPs content increased, which means that the composites were under a quasi-plastic deformation regime. Results from the bonded-interface tests evidenced huge differences in the damage resistance as a function of the graphene source and content. In particular, while monolithic SiC ceramics exhibited well-defined cone cracks beneath the contact zone, the progressive augment of GNPs concentration into the ceramics limited their propagation, associated to an increase in the fracture toughness and, especially, promoted the formation of a quasi-plastic damage zone. As described for ceramic/CNTs composites, the shear faulting process led to the matrix/graphene interface debonding and, consequently, abundant mode II microcracks were generated in the SiC/graphene composites (Fig. 1(b)), being more contact damage resistant than monolithic materials. However, the excessive formation of those microcracks for high GNPs contents (> 10 vol%) produced their coalescence and, hence, favored the substantial removal of material. In other words, its machinability would be enhanced during the grinding processes. The most interesting result of that work is the outstanding behavior of rGOs composites. These fillers, smaller and thinner than GNPs, completely avoided the cone crack formation and exhibited a contact damage response close to that of a ductile material, with an extensive quasi-plastic damage zone (see damage beneath the contact in Fig. 1(a)) where the redistribution of stresses was maximum through numerous short-microcracks that did not coalescence.

Therefore, the contact damage resistance of ceramics can be significantly enhanced by introducing CNTs or graphene-based fillers, which open new opportunities to use these composites in contact-mechanical applications, such as bearings, nozzles, face seal components or wear parts.

Tribological Response of Ceramic/CNTs Composites

The first well-described tribological study performed in ceramic/CNTs composites, in particular in $\text{Al}_2\text{O}_3/\text{MWCNTs}$, was published in by An *et al.* (2003) using a reciprocating ball-on-flat configuration. The dry tests at 25 N, with a Si_3N_4 ball as counterpart, concluded that the addition of 22 vol% of CNTs to an Al_2O_3 matrix reduced the friction coefficient in $\sim 40\%$ as compared to the monolithic ceramics. These authors explained this behavior based on the lubricating properties of the nanotubes and their rolling motion at the interface between both counterparts. This first work initiated a fruitful research line focused on the tribological characterization of ceramic/CNTs composites that extends until now. Some tribological reports on $\text{Al}_2\text{O}_3/\text{CNTs}$ materials followed in the next years (Ahmad *et al.*, 2010; Hvizdos *et al.*, 2012; Lee *et al.*, 2013; Lim *et al.*, 2005; Sharma *et al.*, 2019), and during that time other bulk ceramics filled with CNTs joined to the list, such as hydroxyapatite (HA) (Lahiri *et al.*, 2010; Zhao *et al.*, 2014), Si_3N_4 (Gonzalez-Julian *et al.*, 2011; Gonzalez-Julian *et al.*, 2014; Hvizdos *et al.*, 2012), yttria-stabilized zirconia (YSZ) -both tetragonal 3YSZ (Kasperski *et al.*, 2013; Melk *et al.*, 2015; Shin and Hong, 2012) and cubic 8YSZ (Lamnini *et al.*, 2019)-, SiC (Candelario *et al.*, 2016), SiO_2 (Sharma *et al.*, 2019), as well as Al_2O_3 (Balani *et al.*, 2008; Keshri and Agarwal, 2011) and TiO_2 (Wang *et al.*, 2018) coatings (c- Al_2O_3 and c- TiO_2). Most of these works were carried out employing a ball-on-disk geometry, dry testing conditions and loads from 1 to 60 N with a variety of counterparts (distinct ceramics and stainless steel). Besides, few studies also analyzed the tribological response of the composites under lubrication, such as isooctane, sea water or paraffin oil, looking for specific applications in GDI engines (Gonzalez-Julian *et al.*, 2011; Gonzalez-Julian *et al.*, 2014) or in marine environments (Keshri and Agarwal, 2011).

Table 1 collects tribological results reported for ceramic/CNTs composites. In general, CNTs lubricate the tribosystems and lead to significant decreases in the friction coefficient. Fig. 2(a) summarizes the highest friction coefficient reductions attained in ceramic/CNTs composites due to the incorporation of nanotubes. As it can be seen, the friction reductions and CNTs concentrations cover a wide range of values. Despite it is not easy to compare the tribological behavior of these composites due to its strong dependence with the microstructure of the tested materials and the selected tribological parameters, some ideas can be extracted. For instance, in $\text{Al}_2\text{O}_3/\text{CNTs}$ composites, one of the most studied materials, the best reported results in each work were always attained for composites containing the largest amount of nanotubes analyzed (up to 18–22 vol%, see Table 1). These data would suggest that the lubrication of the tribosystem only takes place when the concentration of nanotubes is elevated. As a matter of fact, Ahmad *et al.* (2010) reached the highest reduction in friction (80%) by adding ~ 18 vol% of MWCNTs (~ 3.9 and ~ 9.5 vol% were the other selected CNTs contents) when tested at 14 N. In the same way, for $\text{Si}_3\text{N}_4/\text{CNTs}$ (Gonzalez-Julian *et al.*, 2014; Hvizdos *et al.*, 2012) and YSZ/CNTs (Kasperski *et al.*, 2013; Lamnini *et al.*, 2019) composites with CNTs amounts in the range of 1.5–15.0 vol%, the lowest friction coefficients (50–75%) were always recorded at the maximum filler content studied (Table 1).

The lubricating capability of CNTs was not only demonstrated in dry tribosystems. For instance, isooctane lubricated $\text{Si}_3\text{N}_4/\text{CNTs}$ plates tested against Si_3N_4 balls up to 200 N (Gonzalez-Julian *et al.*, 2014) also evidenced a significant decrease of the friction coefficient (48%) thanks to the addition of 12 vol% of MWCNTs to the ceramic matrix.

The beginnings of the tribology in ceramic/graphene composites started in 2013, with the works on $\text{Si}_3\text{N}_4/\text{GNPs}$ composites by Hvizdos *et al.* (2013) and Belmonte *et al.* (2013), ten years after the work by An *et al.* (2003) in $\text{Al}_2\text{O}_3/\text{CNTs}$ composites. This delay comes from the later discovery of graphene compared with the nanotubes, although, conversely, the tribological experience acquired with the CNTs composites jointly with their excellent tribological results accelerated the investigations in graphene-based materials. In fact, nowadays, the number of reported works on tribology of ceramic/graphene composites (~ 90) is quite close to those published for ceramic/CNTs ones (~ 100). In spite of the friction results in those initial works on $\text{Si}_3\text{N}_4/\text{GNPs}$ were not very

Abbreviation: NA, not available.

promising (friction coefficient decreased just 11% under isooctane lubrication (Belmonte *et al.*, 2013) or even kept invariable in dry conditions (Hvizdos *et al.*, 2013)), the wear results were quite remarkable (~60% improvement).

At present, Si₃N₄/GNPs composites (Balazsi *et al.*, 2017; Balko *et al.*, 2014; Belmonte *et al.*, 2013; Hvizdos *et al.*, 2013; Llorente *et al.*, 2019; Maros *et al.*, 2016; Rutkowski *et al.*, 2015; Tapasztó *et al.*, 2017) and Al₂O₃/(GNPs or rGOs) composites (Gutierrez-Gonzalez *et al.*, 2015; Hussainova *et al.*, 2016; Kim *et al.*, 2014; Sharma *et al.*, 2019; Yazdani *et al.*, 2015; Zhang *et al.*, 2016) are the most studied materials. In the last years other graphene composites, bulk and coatings (c-), based on SiC (Guo *et al.*, 2019; Llorente *et al.*, 2016; Llorente and Belmonte, 2018; Zhang *et al.*, 2018), B₄C (Sedlak *et al.*, 2017), 3YSZ (Gutierrez-Mora *et al.*, 2019; Zeng *et al.*, 2019), SiO₂ (Porwal *et al.*, 2014; Sharma *et al.*, 2019), c-ZrO₂ coatings (Li *et al.*, 2014), Y₂O₃-Al₂O₃-SiO₂ (c-YAS) coatings (Gomez-Gomez *et al.*, 2016) and CaSiO₃ (c-CS) (Xie *et al.*, 2014) coatings have been tested.

Fig. 2(b) represents the maximum friction coefficient reductions reported in ceramic/graphene composites. Interestingly, unlike CNTs composites where the most suitable filler contents scanned from ~5 to 22 vol%, in the case of graphene composites the filler amounts were below 10 vol%, reaching reductions in the friction that varied from negative values to up to 100%. The addition of lower filler contents in the case of GNPs or rGOs, as compared to CNTs, could be explained by its most effective dispersion into the ceramic matrix than in the case of the nanotubes, which easily agglomerate forming bundles and, hence, higher CNTs contents would be required to achieve similar contributions to the tribological performance. To shed some light about this fact, the friction coefficient reductions of the most interesting oxide (Al₂O₃) and non-oxide (Si₃N₄) ceramics containing both kinds of CNs fillers are compared in Fig. 3(a) and (b), respectively. Al₂O₃/CNs plot (Fig. 3(a)) clearly shows two groups of data: one related to graphene composites with filler contents ≤5 vol% and friction reductions around ~30%, and another one associated to CNTs composites, with nanotube contents between 10 to 22 vol% and friction reductions above 40% and up to 80%. The lack of results with larger graphene contents does not allow making a direct comparison of the friction behavior of these composites with that showed by CNTs ones, although both of them would be equivalent. However, that exercise can be done for Si₃N₄/CNs composites (Fig. 3(b)). If data with negligible or low reductions are not considered, no clear differences as a function of the kind of filler can be established, with overall friction reductions in the 40–60% interval. This suggests that the friction mechanisms would be similar, independently of the type of filler.

Fig. 2 Maximum reduction of the friction coefficient for ceramic/CNs composites as a function of CNTs (a) and graphene (b) fillers content. Plotted data correspond to the best value achieved for each individual work collected in [Tables 1](#) and [2](#). Oxide- and non-oxide-based ceramic composites are represented by empty and full symbols, while half-filled ones correspond to ceramic coatings (c-). An asterisk nearby a symbol indicates a reduction of the friction coefficient above one order of magnitude as compared to the corresponding reference material.

Fig. 3 Maximum reduction of the friction coefficient as a function of CNs content for: (a) Al_2O_3 /CNs and (b) Si_3N_4 /CNs composites. Plotted data correspond to the best value achieved for each individual work collected in [Tables 1](#) and [2](#). Full and empty symbols correspond to composites containing CNTs and graphene-based (GNPs or rGOs) fillers, respectively.

In general, when any material is tribologically tested at macro-scale (loads above 1 N), the friction evolution is on line recorded during the experiments and, afterwards, the wear volume is calculated by measuring the dimensions in 2D and/or 3D of the wear tracks. Less frequent is to use the wear loss parameter, which is estimated from differences in the specimen weight. The wear volume (W_V) or the wear rate (W_R), the latter assessed from the equation $W_R = W_V \cdot P^{-1} \cdot d^{-1}$, where P and d are the applied load and the tested distance, respectively, allow estimating the wear resistance performance of the materials. Most of works previously cited in the friction coefficient section also reported W_V or W_R data. Although the friction results achieved by adding CNs fillers to ceramic matrices are, in general, good enough, the wear response is much more encouraging. Actually, the majority of ceramic/CNs composites exhibit wear resistance improvements above 45% ([Fig. 4](#)), with numerous examples showing increases higher than 80%, and reaching in some cases W_R reductions close to two-three orders of magnitude for different ceramic composites and fillers (i.e., 8YSZ/2.9 vol% CNTs ([Lamnini et al., 2019](#)), 3YSZ/2.5 vol% GNPs ([Gutierrez-Mora et al., 2019](#)), and Si_3N_4 /7.8 vol% GNPs ([Tapasztó et al., 2017](#))). Authors relate this outstanding response to the formation of an adhered and continuous tribofilm based on CNs that protects against wear, and to the improvement in the mechanical properties of the composites as compared to the monolithic ceramics.

It is worth mentioning that a decrease in the friction coefficient for a specific ceramic composite and CNs filler content is not always synonym of a better wear resistance, or vice versa. In fact, when comparing data collected in [Tables 1](#) and [2](#) within the same

Fig. 4 Maximum improvement of the wear resistance for ceramic/CNs composites as a function of CNTs (a) and graphene-based (b) fillers content. Plotted data correspond to the best value achieved for each individual work collected in [Tables 1](#) and [2](#). Oxide- and non-oxide-based ceramic composites are represented by empty and full symbols, while half-filled ones correspond to ceramic coatings (c-). An asterisk nearby a symbol indicates a reduction of the wear resistance above one order of magnitude as compared to the corresponding reference material.

reported work, almost the half of the studies found that the best filler content for achieving the highest friction reductions did not match with the necessary CNs amount to promote the largest wear resistances. This trend has been observed for any ceramic matrix or type of filler and can be related to differences in the role played by CNs in the friction and wear mechanisms.

Friction and Wear Mechanisms in Ceramic/CNs Composites

There are many issues that affect the tribological response of materials. Some of them are related to the tribosystem, such as the testing conditions (load, lubrication, counterpart, speed...) and the third body (formed by all materials separating the counterparts such as debris, lubricants...); and some others are closely linked to the properties of the counterparts. The mechanical properties like hardness (H), elastic modulus (E), and fracture toughness (K_{IC}) stand out within this group, being especially important when fatigue and microfracture processes take place. Moreover, their impact on the wear response highly depends on the wear regime. While H and E have a decisive role in mild wear stages ([Hsu and Shen, 2004](#)); K_{IC} is extremely important for severe wear regimes ([Evans and Wilshaw, 1976](#)). The thermal conductivity of the materials can also influence the tribological performance, for instance, by dissipating the local heat at the tribocontacts, modifying the tribochemical conditions (i.e., oxidation), or reducing the thermal shock stresses and, hence, the cracks nucleation ([Hsu and Shen, 2004](#)). Finally, the electrical properties can contribute to some extent to the wear mechanisms. In this way, insulators could trap at the vacancies or grain boundaries the electrical charges generated during the motion of the counterparts, increasing the polarization energy and causing their dielectric breakdown and wear and, conversely, electrical conductors could easily release those charges and avoid this kind of wear ([Belmonte et al., 1996](#)). In the case of ceramic/CNs composites, carbon fillers improve many of these structural and functional properties ([Azamiya et al., 2017](#); [Miranzo et al., 2017](#)), although probably the key issue in the tribological process is the third body formation.

There is a general consensus within the tribology community that both CNTs and graphene-based fillers promote the decrease of the friction coefficient of ceramics due to their lubricating characteristics. In essence, CNs are pulled out from the composite during the tribotests and, then, crushed into debris due to the action of the microabrasion mechanism. Those debris are progressively compacted to form a self-lubricant carbon-rich tribofilm on the mated surfaces ([Fig. 5](#)). Sometimes, CNTs protruding from the composite surfaces have also been observed ([Ahmad et al., 2010](#)), which would act as lubricious rollers ([Fig. 6\(a\)](#)); whereas GNPs can be exfoliated into smaller and thinner flakes ([Belmonte et al., 2013](#)), contributing to the tribofilm ([Fig. 6\(b\)](#)).

According to [Wang et al. \(2018\)](#), there are four kinds of frictional effects of CNTs ([Fig. 7](#)): (1) tribo-protruding where CNTs are pulled-out from the composite surface and crushed; (2) tribo-reorientation of the lower aspect ratio CNTs that perpendicularly rotate to the sliding direction, a layout more effective to reduce the friction; (3) tribo-film, a lubricant layer formed by short and smeared CNTs and ceramic debris that substantially decrease friction and; (4) tribo-degradation of the CNTs due to the high shear forces attained during the whole test. These frictional effects can also be extended to GNPs, with maybe the unique exception of the tribo-reorientation.

[Belmonte et al. \(2013\)](#) employed for the first time the micro-Raman spectroscopy to investigate the tribofilm composition formed in Si_3N_4 /GNPs composites. CNs essentially exhibit three intense characteristic Raman bands: D ($\sim 1360 \text{ cm}^{-1}$), G ($\sim 1594 \text{ cm}^{-1}$) and 2D or G' ($\sim 2717 \text{ cm}^{-1}$). Moreover, if the ceramic matrix also has a clear Raman signature, the composition of the wear debris into the wear tracks could be established. [Fig. 8](#) illustrates how micro-Raman spectroscopy contributes to go in depth in the tribofilm characterization. In this example, the Raman spectrum points the main bands for SiC and GNPs in the

^aFor a better comparison, graphene volume contents were employed and estimated if published data referred just to the weight percentage. Fillers mostly correspond to GNPs. When using rGOs, the information is specified.

Abbreviation: BS, borosilicate; NA, not available; SS, stainless steel.

pristine SiC/GNPs composite (Fig. 8(a)). By selecting the most intense bands for the matrix and the filler, it was possible to create a false colored image (blue for SiC-TO band and red for G band) of the untested and tribological tested surfaces as a function of the GNPs content (Fig. 8(b)). In this tribosystem, the composite with the largest amount of GNPs was able to develop a uniform and continuous tribofilm (see differences between the images for untested and tested specimens in Fig. 8(b)) that was formed by some SiC debris and, especially, by carbonaceous material, which strongly contributed to reduce the friction (Llorente *et al.*, 2016). Furthermore, the intensity ratio between D and G bands (I_D/I_G) can be used to estimate the defects degree of CNs species and, in this way, an increase in I_D/I_G would correspond to more defective nanostructures. As Fig. 8(b) shows, I_D/I_G augmented after testing the materials due to the crushing and exfoliation processes of the pulled-out graphene stacks, being more extensive (higher I_D/I_G) when the complete tribofilm was formed. The exfoliation degree of GNPs was also studied by micro-Raman spectroscopy taking into account the intensity ratio between 2D and G bands (I_{2D}/I_G). In this case, an increment of this value would confirm a decrease in the number of layers forming the GNPs, or in other words, a higher exfoliation degree (Belmonte *et al.*, 2013). Actually, Raman maps of Si₃N₄/GNPs composites (Fig. 8(c)) evidence the presence on the worn surfaces of a considerably number of features with high I_{2D}/I_G values -in yellow color- as the tested load increased. Considering that the wear volume of this composite remained almost invariable with the load, this fact would support that GNPs are more exfoliated and highly contribute to the development of the tribofilm. Therefore, nowadays, micro-Raman spectroscopy has become into an essential tool for the tribological characterization of ceramic/CNs composites and numerous studies currently employ it.

Despite the tribofilm has also been observed when using external lubrication, its formation mechanism depends on the lubricating media. In this way, Al₂O₃/CNTs coatings tested against Si₃N₄ balls in sea water (Keshri and Agarwal, 2011) showed a reduced friction and higher wear resistance due to the formation of a SiO₂-rich protective layer coming from tribochemical reactions in the Si₃N₄ ball, a higher fracture toughness of CNT-reinforced coating, and the antifriction effect of sea water. In

Fig. 5 Scanning electron micrographs of the tribolayer formed on $B_4C/6$ wt% GNPs composites after testing at 50 N: (a) top and (b) cross-section views showing a homogenous and compacted tribolayer with thickness around 2–3 μm . Effect of graphene platelets on tribological properties of boron carbide ceramic composites. *International Journal of Refractory Metals and Hard Materials* 65, 57–63.

Fig. 6 Scanning electron micrographs of the worn $Al_2O_3/CNTs$ (a) and $Si_3N_4/GNPs$ surfaces (b) showing CNTs protruding from the composite and exfoliated GNPs-based debris, respectively. Adapted from Ahmad, I., Kennedy, A., Zhu, Y.Q., 2010. Wear resistant properties of multi-walled carbon nanotubes reinforced Al_2O_3 nanocomposites. *Wear* 269, 71–78. Belmonte, M., Ramirez, C., Gonzalez-Julian, J., *et al.*, 2013. The beneficial effect of graphene nanofillers on the tribological performance of ceramics. *Carbon* 61, 431–435.

$Si_3N_4/GNPs$ composites tested against SiC under water lubrication (Zhang *et al.*, 2018), the friction strongly decreased due to the combined effect of a carbon-containing surface layer and the stabilization of a water film between the counterparts. On the other hand, the decrease in the friction of isooctane lubricated $Si_3N_4/GNPs$ composites was attributed to the development of a double tribolayer (Llorente *et al.*, 2019). This tribolayer was formed by an inner thin transfer film containing isooctane and ultrafine wear debris, and an outer thick self-lubricant carbonaceous tribofilm coming from the pulling-out and crushing of GNPs and oxidized Si_3N_4 particles.

The wear resistance of a tribosystem is closely linked to the protection provided by the tribolayer and the mechanical properties of tested materials. In fact, the mechanical stresses attained at the tribocontact are the responsible for the destabilization and partial -or total- removal of that tribolayer, wearing the contact surfaces and reducing the wear resistance. Those mechanical stresses depend on many factors but are especially promoted under dry testing conditions, where severe wear usually occurs. In this way, an enhanced wear resistance is commonly attributed to the improved fracture toughness of CNs composites as compared to monolithic ceramics.

Fig. 7 Schematic illustrating the frictional effects of CNTs (tribo-protruding, tribo-reorientation, tribo-film, and tribo-degradation) on TiO_2/CNTs coatings. Adapted from Wang, H.-D., He, P.-F., Ma, G.-Z., *et al.*, 2018. Tribological behavior of plasma sprayed carbon nanotubes reinforced TiO_2 coatings. *Journal of the European Ceramic Society* 38, 3660–3672.

CNTs fillers arrest or limit the propagation of cracks developed beneath the tribocontact through the occurrence of toughening mechanisms such as crack deflection, bridging or branching (Ahmad *et al.*, 2010; Candelario *et al.*, 2016; Lamnini *et al.*, 2019). The micromechanical response and the contact damage resistance are also important, as the stress fields generated can be redistributed by the fillers located at the grain boundaries (Gonzalez-Julian *et al.*, 2011), restraining the formation of long cracks.

Hsu and Shen (2004) established that, under mild wear conditions, W_R of ceramics is inversely proportional to the product of H and E . Thus, considering that these mechanical parameters decrease with the CNTs additions in most of composites (Azamiya *et al.*, 2017; Miranzo *et al.*, 2017), a loss of the wear resistance in ceramic/CNTs composites would be expected. However, Llorente and Belmonte (2018) and Llorente *et al.* (2019) found that the development of an homogenous and well adhered lubricating carbon-based tribolayer on ceramic/GNPs surfaces was able to counterbalance the negative impact of their mechanical properties in the wear behavior. Actually, the wear resistance enhanced in $\text{Si}_3\text{N}_4/\text{GNPs}$ and SiC/GNPs composites until their respective tribolayers were destabilized due to an increment in the tensile stresses.

Nanotubes or Graphene?

One interesting question is to decide what kind of CNTs filler -nanotubes or graphene- is more attractive from the tribological point of view. Obviously, their dimensions (length/diameter for CNTs or thickness/lateral size for graphene) and number of layers (rolled or stacked) can modify the friction and wear responses of the CNTs composites. In addition, the only way to answer that question is to compare the same composites (composition, grain size, density, CNTs dispersion...) by replacing one filler by the same content of another one, and using identical testing conditions. Fig. 9 plots the steady state friction coefficient (Fig. 9(a)) and W_V (Fig. 9(b)) of $\text{Si}_3\text{N}_4/\text{MWCNTs}$ and $\text{Si}_3\text{N}_4/\text{GNPs}$ composites containing 3 wt% of fillers (~ 5 vol%). These materials were tested at different loads employing a reciprocating ball-on-plate configuration mated against Si_3N_4 balls under lubrication with isooctane. At first glance, CNTs provide a higher lubrication than GNPs, exhibiting a lower friction coefficient for all range of loads than the reference ceramics; while GNPs are able to reduce the friction of Si_3N_4 only at the maximum tested load. Interestingly, the friction curves for CNTs and GNPs composites are almost parallel but shifted to higher friction values in the latter material. It seems that nanotubes are easier pulled-out from the matrix than the nanoplatelets, quickly contributing to the development of a continuous lubricating tribolayer; whereas GNPs need more severe testing conditions to promote a similar mechanism. Both composites are more wear resistant than monolithic ceramics, all materials running under a mild wear regime ($W_R \sim 10^{-8} \text{ mm}^3 \text{ N}^{-1} \text{ m}^{-1}$). Once more the tribolayer plays an active role in the wear behavior. While at low and intermediate loads a compacted and stabilized wear protecting tribolayer was formed on CNTs composite, limiting the wear compared to GNPs materials, at high loads that tribolayer became unstable for CNTs, GNPs composite being now that with the best wear performance. Moreover, its W_V value remained almost invariable with the load, which clearly reflects that the tribolayer is formed by the continuous exfoliation of pulled-out nanoplatelets. Lahiri *et al.* (2010) also

Fig. 8 Raman characterization of the tribolayer formed on ceramic/GNPs composites. (a) Raman spectrum of the untested SiC/GNPs composite with the main characteristic bands for SiC and GNPs, and (b) false colored Raman images for monolithic SiC and two composites containing 5 and 20 vol% of GNPs. The left hand column is for untested materials, while the right hand one is for tested surfaces. Features in blue and red are ascribed to SiC and GNPs. I_D/I_G values are also included for each image. (c) false colored Raman images representing I_{2D}/I_G in worn Si₃N₄/GNPs surfaces composites tested at 50 and 200 N. The bright yellow spots correspond to highly exfoliated GNPs (high I_{2D}/I_G values). Adapted from Belmonte, M., Ramirez, C., Gonzalez-Julian, J., *et al.*, 2013. The beneficial effect of graphene nanofillers on the tribological performance of ceramics. *Carbon* 61, 431–435. Llorente, J., Belmonte, M., 2018. Friction and wear behavior of silicon carbide/graphene composites under isooctane lubrication. *Journal of the European Ceramic Society* 38, 3441–3446.

observed that the shear stress level reached during the tests controls the tribological behavior. In that work, CNTs were removed from hydroxyapatite composites during macro-wear conditions, lubricating the system and reducing the friction but, conversely, using nano-wear parameters, the peeling action of the CNTs did not occur and the friction augmented.

Within the graphene-based category, GNPs and rGOs fillers can be distinguished. At present, there is just one work, reported by Llorente *et al.* (2016), where the effect of the graphene source on the tribological properties of ceramic/graphene composites was investigated. For the same volume content (5%), authors found better friction results of SiC/graphene composites when used GNPs instead rGOs. GNPs seem to be more easily removed, exfoliated, and crushed than rGOs, creating a compacted carbon-based tribolayer, which was not fully developed for rGOs. However, the wear resistances for both composites were very similar, slightly higher for rGOs. In this case, the lack of a well-formed tribolayer in rGOs composite was counteracted by its larger fracture toughness.

To conclude, both CNTs and GNPs tend to act as self-solid lubricants in ceramic/CNs composites through the formation of a carbonaceous-based tribolayer that can also protect against wear. The ability of each tribosystem to pull-out and crush the CNs into debris to create a stable tribolayer will depend on the testing conditions and properties of the materials, especially the

Fig. 9 Tribological behavior of Si₃N₄/CNs composites for the same filler (CNTs and GNPs) content (~5 vol%): (a) friction coefficient and (b) wear volume. Data replotted from Belmonte, M., Ramirez, C., Gonzalez-Julian, J., *et al.*, 2013. The beneficial effect of graphene nanofillers on the tribological performance of ceramics. Carbon 61, 431–435. mechanical ones. The wear response will depend on the balance between the stabilization of the tribolayer and the fracture toughness behavior, for severe wear regimes, or against the combination of hardness and elastic modulus, in the case of mild wear regimes commonly achieved for lubricated tribosystems. Finally, ceramic/CNs composites are very promising materials to be used under demanding tribological applications in many fields, from transportation to energy, including electronics or health.

Methods of Determination of Young's Modulus and Tensile, Flexural and Compressive Strength

Sylvain Meille, University of Lyon, Lyon, France

General Introduction

This chapter aims at describing the main experimental methods used to determine critical mechanical parameters for ceramics: Young's modulus and fracture strength. The determination of fracture toughness, although a critical parameter for structural materials, will not be considered here.

Ceramic materials have stiff interatomic bonds and therefore high values of Young's modulus E (typically several hundreds of GPa), associated to high melting temperatures, these two properties being linearly correlated. This high stiffness explains that ceramic components show limited deformation when submitted to mechanical loadings. Glasses show Young's modulus ranging typically from 10 to 160 GPa (Rouxel, 2006). Ceramics and glasses can be found in their porous form in many multifunctional applications, with a total porosity fraction ranging from 0% to more than 90%. Young's modulus is in that case strongly dependent on the porosity fraction (Rice, 1998) and can be as low as 1 MPa of silica aerogels with porosity fraction above 90%. It is also worth mentioning concrete, as the largely used material in volume in the world, with a typical value of E of 30 GPa.

The fracture strength of ceramics is also high, typically of several hundreds of MPa in tension, and several GPa in compression in the case of dense ceramics. Ceramics and glasses usually show a linear elastic behavior until sudden fracture, at least at room temperature. The experimental scatter in fracture strength is relatively high as compared to ductile materials such as metals or polymers. This has a strong influence of the mechanical analysis for ceramic components in order to ensure a minimal probability of failure (Danzer *et al.*, 2008; Bermejo and Danzer, 2014). The porosity fraction has logically a deleterious influence of the fracture strength (Sanahuja *et al.*, 2010; Colombo *et al.*, 2013).

Determination of Young's Modulus

Definition

Elastic moduli link stresses and strains in the elastic domain, when no irreversible macroscopic deformation is noted, hence associated to small applied strains, typically below 0.1%. Young's modulus is defined as the ratio between axial (in the direction of solicitation) stress and axial strain in uniaxial tests, Poisson's ratio as the opposite of the ratio of lateral strain to axial strain. Shear modulus is the ratio of shear stress to shear strain in shear loadings. Bulk modulus is the ratio of hydrostatic pressure to hydrostatic volume variation in hydrostatic tests.

For isotropic materials, only two independent constant are needed to describe its entire elastic properties. Usually, Young's modulus E and Poisson's ratio ν are used, but bulk modulus K and shear modulus G are also commonly used. These latter moduli are related to the former one using the following equations:

$$K = \frac{E}{3(1-2\nu)}, G = \frac{E}{2(1+\nu)}, E = \frac{9KG}{G+3K} \text{ and } \nu = \frac{E}{2G} - 1$$

Fig. 1 illustrates the flexibility tensor (inverse of the stiffness tensor) for an isotropic material linking stress and strain tensors.

Ceramic based materials can be anisotropic, as in the case of composites (such as long fibers ceramic matrix composites), porous materials (3D printed structures, freeze-cast materials), or bio-inspired materials (nacre-like ceramics). They usually show an orthotropic behavior, with 3 different values of Young's modulus, Poisson's ratio and shear modulus in three orthotropic directions, and a total number of unknown engineering constants of 9. For transverse isotropic materials, the entire stiffness tensor can be determined with 5 parameters. Most of the experimental data of elastic modulus for anisotropic ceramic materials focus on the stiffer direction. Testing monocrystalline materials also leads to anisotropic behavior, possibility with more than 9 independent constants, depending on the nature of the ceramic. The readers are advised to refer to the classic book of Nye (1985), or to a composite design reference book (Tsai and Melo, 2015). It is always possible to average any anisotropic stiffness tensor to get isotropic parameters representative of an isotropic polycrystalline material. Experimental methods for the determination of elastic modulus mainly focus on the determination of E . For Poisson's ratio, values are usually between 0.25 and 0.3 for dense ceramics, for glasses a large range of value is noted (Greaves *et al.*, 2011).

This section on the determination of Young's modulus is divided into vibration methods and direct methods (static mechanical testing) to determine elastic modulus and especially the Young's modulus.

Vibration Methods

These methods give access to dynamic moduli, usually measured at high frequencies (typically above 1 kHz) and at a low associated strain. They are more accurate methods as compared to direct methods.

$$\begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{22} \\ \varepsilon_{33} \\ \varepsilon_{23} \\ \varepsilon_{13} \\ \varepsilon_{12} \end{bmatrix} = \begin{bmatrix} \frac{1}{E} & -\frac{\nu}{E} & -\frac{\nu}{E} & 0 & 0 & 0 \\ -\frac{\nu}{E} & \frac{1}{E} & -\frac{\nu}{E} & 0 & 0 & 0 \\ -\frac{\nu}{E} & -\frac{\nu}{E} & \frac{1}{E} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{2(1+\nu)}{E} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{2(1+\nu)}{E} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{2(1+\nu)}{E} \end{bmatrix} \begin{bmatrix} \sigma_{11} \\ \sigma_{22} \\ \sigma_{33} \\ \sigma_{23} \\ \sigma_{13} \\ \sigma_{12} \end{bmatrix}$$

Fig. 1 Representation of the flexibility tensor for an isotropic material (components expressed as a function of Young's modulus E and Poisson's ratio ν). The stiffness tensor is the inverse of the flexibility tensor. Reminder: σ_{ij} and ε_{ij} are the stress and strain component respectively. If $i = j$, this corresponds to tension or compression for stresses, and dilatation/contraction for strains. If $i \neq j$, it corresponds to shear stresses and angle distortion for strains.

Ultrasonic propagation

This method is based on the measurement of longitudinal and transversal waves speed in the sample using piezoelectric transducers. Two methods exist: the transmission method where two transducers are used (one to excite, the other to detect waves), and the pulse echo method where the same transducer excites and detects the wave after reflection on the back face of the specimen. From the time record and the dimensions of the specimens, the calculation of the elastic moduli is possible.

For isotropic materials, the measure of longitudinal and transversal speeds gives access to the two independent constants describing the stiffness tensor of the material.

For Young's modulus determination:

$$E = \rho \left(\frac{3V_L^2 V_T^2 - 4V_T^4}{V_L^2 - V_T^2} \right)$$

with ρ bulk density in kg m^{-3} , and V_L and V_T wave speeds in m s^{-1} for longitudinal and transversal waves respectively.

For Poisson's ratio:

$$\nu = 0.5 \left(\frac{V_L^2 - 2V_T^2}{V_L^2 - V_T^2} \right)$$

The shear modulus is logically only related to the transverse wave speed: $G = \rho V_T^2$.

Anisotropic materials can also be characterized in terms of elastic moduli, depending on the ability to produce samples oriented along the different directions of symmetry. Wave propagation allows the determination of all components of the stiffness tensor of single crystals, whatever their crystalline symmetry (Watt and Peselnick, 1980). An estimation of an average stiffness of a dense and isotropic polycrystal can then be performed (Meille and Garboczi, 2001).

The method needs specimens with a well-defined geometry and a controlled surface state (need of two homogeneous, flat and parallel surfaces). The use of coupling agent or of a clamping system between transducers and sample ensures the good wave excitation of the sample. Testing small samples may be delicate as sensors are relatively large, typically 1 cm in diameter. Accuracy of the measure is usually of a few percent (EN843-2, 2005).

Free and forced vibration

In this method, a sample is submitted to an external solicitation, simply standing on a support in the case of free vibration, and suspended on wires for forced vibration. The typical frequency range lies from 0.1 to 100 kHz. As for the ultrasonic wave propagation, this method is accurate and well adapted to ceramics and glasses, usually showing limited damping at room temperature. The measure is based on the determination of the resonant frequency, related to samples moduli, dimensions and weight. The damping properties of a material can be characterized with this technique, either by measuring the width of the resonance peak for forced vibration, or by the analysis of decaying fundamental frequency for free vibration.

This measurement method needs samples with a well-defined geometry (bars are the most common, rods are also possible for flexion resonance) and smooth surfaces. A parallelism of the surfaces to approximately one hundredth of the corresponding sample's dimension is needed. Using flexion and torsion resonance, it is possible to determine Young's and shear modulus respectively. The Poisson's ratio can therefore be calculated from E and G . An important caution is necessary on the nature of vibration modes activated (mainly flexion versus torsion modes). The nodes for fundamental resonance in flexion are located at $0.224 l$ from each end of the sample, l being the sample length. For fundamental resonance in torsion, the nodes are located at mid-length and at mid-width of the sample (EN843-2, 2005).

Fig. 2 Forced vibration method for the determination of elastic moduli, position of the wires used for excitation and for detection (a) flexural mode, (b) torsional mode.

For bars, a ratio of sample's length l to thickness h (in the direction of the flexural vibration) above 10 is recommended for flexion resonance, and above 20 for torsion resonance. In addition, a ratio of the length l on the width b should also be above 10. A ratio of width b to height h , b/h above 1.1 or below 0.9 is recommended to avoid confusion between vibration modes, typical values being $2.5 < b/h < 10$. It is therefore critical to pay attention in differencing b and h values when using the formulas.

Fig. 2 illustrates the testing specifications for flexion and torsion resonance for forced vibration.

Forced vibration

The sample is usually held by wires that drive and detect vibration. The wires must be positioned at the vibration nodes (see **Fig. 2**). For torsion resonance, the wires should be placed near the extremities, at the diagonally opposite corners. To ensure that a torsion mode is excited, possibly use a small microphone and move along the sample's length. The resonance should disappear at the center of the sample if it is torsional.

Impulse excitation method (free vibration)

The sample is supported at its nodes (i.e., at $0.224 l$ for bending mode, and at mid-length and mid-thickness for torsion mode) and mechanically excited by a light tap. The natural frequency of vibration is detected by a piezoelectric transducer or by a microphone. For flexion resonance, two parallel and compliant supports are located at the nodes and for torsion resonance at the center (specific support with a shape of a cross is usually supplied). The impact location should be at the centerpiece for flexion and at one corner of the sample for torsion. The position of the transducer should be either at the maximum vibration of the sample (near the ends, at mid-width for flexion and at a corner for torsion).

Apparatus for impulse excitation exist for high temperature up to 1500°C . The measure is also possible on disk shaped specimens (with a diameter to thickness ratio above 10). In that case, by exciting two different modes of vibration (symmetric mode and folding mode) can give access to the Poisson's ratio. If only one mode is activated and the Poisson's ratio is known, one can have access to the Young's modulus. Shear modulus can then be calculated, see (EN843-2, 2005) annex A for more details.

The same formulas for the calculation of moduli are used for both forced and free vibration techniques. For flexion resonance, the Young's modulus E is determined using equation:

$$E = 0.946 \left(\frac{mf^2}{b} \right) \left(\frac{l}{h} \right)^3 \left(1 + 6.585 \left(\frac{h}{l} \right)^2 \right)$$

with m mass of the sample, f resonance frequency of the fundamental mode, l , b and h length, width and height of the sample respectively. The last factor of the equation is a shape factor.

For torsional resonance, the equation to calculate the shear modulus G is (assuming $b > h$):

$$G = \left(\frac{4lmf^2}{bh} \right) \left(\frac{\frac{h}{b} + \frac{b}{h}}{4 \frac{h}{b} - 2.52 \left(\frac{h}{b} \right)^2 + 0.21 \left(\frac{h}{b} \right)^6} \right)$$

with f the resonant frequency in torsion, the other parameters being identical to the formula in flexion. The last factor in the equation is a shape factor.

Many other experimental methods exist to measure elastic properties, such as atomic force microscope AFM resonance or tapping modes, spectroscopy and diffusion / diffraction methods (Brillouin spectroscopy, neutrons and X-ray diffraction X-ray diffraction...). A detailed description of these techniques is beyond the scope of this chapter. The reading of the review paper by Angel *et al.* (2009) is recommended.

It is noteworthy to detail *resonant ultrasound spectroscopy (RUS)* as a complementary technique to those describe in this chapter. This technique is largely used in Earth sciences for the characterization of rocks. A sample is held between two piezoelectric sensors (a driver and a monitor), allowing the determination of different vibration frequencies in a single measure. Data reduction and

mode analysis usually take more time than the measure itself. This method is well adapted for anisotropic materials. To allow the determination of an anisotropic tensor with a single measurement, the sample needs to have a precise shape (sphere, or parallelepiped), polished surfaces, and being preferably dense. The sample characteristic size ranges typically from 1 mm to 1 cm. Measurements are possible up to 1500°C.

Direct Methods

These methods are based on the determination of the stress-strain linear relationship in a uniaxial mechanical test. They are largely used for determining elastic modulus, however they are not always adapted to ceramics due to the limited deformation to be measured, related to their high rigidity, and therefore to the difficulty to precisely measure the displacement of the sample.

General considerations

As mentioned here above, the determination of the displacement (and subsequently of the deformation) is particularly critical in the determination of elastic moduli on stiff specimens. The use of the crosshead displacement during mechanical tests is most of the time not precise enough to achieve a precise determination of E and it can lead to large errors in the elastic modulus determination. A proper displacement measurement can be made using:

- (1) Sensors, such as extensometers, LVDT (linear variable differential transducers), or strain gauges glued on sample's surface. These show a typical resolution 1 μm and less. Sensors for high temperature measurement exist, with alumina guides. It is also possible to use the crosshead displacement but only associated to a careful determination of the system stiffness (including contributions of the machine frame, the load cell, and the specific equipment) using a reference material with known elastic modulus.
- (2) Digital Image Correlation (Hild and Roux, 2006). This technique allows the characterization of the displacement field at the surface of samples during testing, using an appropriate measurement chain (video camera and objective), possibly at high temperature (Lepay et al., 2012). The calculation of the strain field is then possible from the displacement field. To improve the accuracy of the measurement, a regularization of the strain field can be used when known displacement fields corresponding to specific loading case are available. This is typically the case for tension/compression, flexion, and torsion. This enable to quantify the amount of rotation or of secondary bending in a tension test for example, and then to extract the relevant strain field corresponding to the pure tension loading.

The choice of a relevant load cell capacity is critical as the load values must lie in the measurement range of the cell, i.e., typically above 1% of the total capacity of the cell, this value being largely dependent on the cell quality.

For the stress and strain calculation, due to the high stiffness of ceramics and glasses, small deformation hypothesis is usually considered as valid. Engineering stresses and strains can be used instead of real stresses and strain. As shown hereafter, the main source of errors in the determination of elastic moduli and fracture stress, apart from the displacement measure, are the imperfections during testing.

Sample size

To test a representative elementary volume (REV), the rule of thumb is that the smallest dimension of the sample should be at least ten time the size to the largest heterogeneity of the material.

Uniaxial tension tests

This test implies a uniform axial solicitation, homogeneous in the central part of the sample, usually with a reduced cross-section, leading to an easy calculation of stresses and strains from the load and displacement values. The main concern is the possible imperfection during loading, mainly related to alignment issues. In that case, an additional bending moment can be applied to the sample. Therefore, an important care is necessary when designing a tensile test equipment. A more detailed description of the test is proposed in next section on the tensile fracture strength determination.

Using tensile test is certainly not the method to only measure E , due to the difficulty to run a well-controlled test. Tension tests are first carried out to determine tensile strength (see Section "Uniform Tests") and secondary to determine the Young's modulus.

Uniaxial compression tests

This test also leads to a uniform solicitation in the sample and therefore an easy determination of stress strain curves. However, experimental issues exist during uniaxial compression testing, mainly at the contact zones between top and bottom surfaces of the sample and the loading platens. As for uniaxial tension testing, more details on the experimental procedure are given in the compression strength determination (see Section "Uniform Tests").

A possible non-perfect parallelism of the top and bottom surfaces of the sample as well as the surface roughness always lead to stress concentrations that generate local irreversible damage. This results in non-linear behavior in the load – displacement curve. It is recommended to carefully prepare the samples and possibly to polished the surfaces in contact with the loading platens.

Running loading/unloading cycles in the elastic domain is the preferred method to estimate the slope of the stress strain curve, avoiding the influence of local damage and the non-perfect geometry of samples. This is particularly important for porous

Fig. 3 Schematic representation of a 4 point bending test.

materials for which damage at the contact zone strongly influences the load-displacement curve. In that case, incorrect measurement of the slope of stress strain curve could lead to important errors in the determination of the Young's modulus, with a calculated value much smaller than the real one.

In some cases, the Young's modulus determined in compression may be smaller (typically 10% less) than the Young's modulus measured in tension. This is usually the case for micro-cracked materials (Lepay *et al.*, 2010; Belrhiti *et al.*, 2012; Bruno *et al.*, 2012). The material's behavior is then not perfectly elastic even though the macroscopic load-displacement curve appears linear. In such cases, the non-linear behavior is often more pronounced in tension tests (due to an easier opening of microcracks). The use of acoustic emission sensors to record elastic waves generated by local damage events is an efficient technique to define the stress or strain threshold above which damage is generated in the sample.

Bending tests

Flexion or bending testing is the preferred direct method to estimate the Young's modulus in ceramics and glasses, this for several reasons: no gripping of the samples unlike in tensile tests, no contact friction unlike in compression tests, and a rather large displacement of the sample (deflection) due to the low specimen stiffness in bending. However, experimental issues exist in bending, and the testing equipment should account for a non-perfect parallelism between top and bottom faces of bars (the most commonly used sample geometry).

The determination of the Young's modulus (as well as of the fracture stress, see Section "Determination of Fracture Strength") is based on the assumption of a symmetric behavior in tension and compression of the material, leading to a neutral axis located at mid-height of the sample. This assumption is considered to be valid for dense ceramics and glasses. For more details about the calculation of stresses and strains in bending, reference books such as Timoshenko (1955) are recommended. Here, only the formula to determine E is given. Fig. 3 illustrates a 4 point bending test configuration on a bar.

In the case of deflection measured at the center (mid-length) of the sample, E is given by:

$$E = \frac{\Delta P}{\Delta u} \frac{(l_{lower} - l_{upper}) (2l_{lower}^2 + 2l_{lower} \cdot l_{upper} - l_{upper}^2)}{8bh^3}$$

with u the deflection measured at the center of the specimen, P the applied load, l_{lower} and l_{upper} the distance between lower and upper rollers respectively, b the sample width, h the sample height. For 3 point bending, the equation is valid when considering $l_{upper} = 0$.

In the case of deflection measured on the loading points:

$$E = \frac{\Delta P}{\Delta u} \frac{(l_{lower} - l_{upper})^2 (l_{lower} + 2l_{upper})}{4bh^3}$$

with the same parameters as the previous equation.

The former equations are based on beam theory, and are valid under specific assumptions. In particular, the influence of shear stresses is neglected. This is considered as valid if the ratio of the lower span (or distance between lower rollers l_{lower}) to the sample's height, also referred as the slenderness, is large enough, typically above 8. If not, the additional deflection term caused by shear stresses as to be taken into account as it affects the Young's modulus determination. This influence can be taken into account by multiplying the Young's modulus determined without the influence of shear stresses by a factor χ :

$$\chi = 1 + \frac{(1 + \nu)h^2}{2l_{lower}^2 + 2l_{lower} \cdot l_{upper} - l_{upper}^2}$$

with the same parameters as the above equation, and ν the Poisson's ratio.

In case of large deflection during testing (for example for very thin samples or for a low stiffness material), the upper and lower roller distance may increase during the test, leading to a modification of the stress and strain in the material. In that case, possible friction may occur at the sample/roller interface. When testing materials that can damage under localized loading, wedging may occur below the rollers, affecting the measurement of the deflection. This effect is more pronounced with rollers of small diameter. A typical roller diameter of 3 mm is therefore recommended.

Fig. 4 Schematic representation of an instrumented indentation test, load – displacement curve and cross section of tip and sample during contact.

Corrections are proposed in literature to take into account these effects (Mitchell *et al.*, 2009). As an example, classical Hertz theory of elastic contact enables to correct the indentation influence of the roller (Quinn and Morrell, 1991; Munz and Fett, 1999). Identification of actual boundary conditions during testing is possible using regularized digital image correlation (Leplay *et al.*, 2010; Bouterf *et al.*, 2015).

The formulas given here above are also based on the hypothesis of symmetry between tension and compression stresses and strains in the sample, i.e., a neutral axis located at mid-height of the sample. If this is often respected during bending tests on dense ceramics and glasses, it is not the case for all materials, as in microcracked materials, stiffer under compression stresses that tend to close cracks than under tension stresses that tend to open them. In the case of a Young's modulus in tension lower than in compression, the neutral axis is not located at mid-height of the sample. Previous formulas for the determination of E are not valid anymore. Then, a precise determination of the position of the neutral axis is necessary, possibly using strain gages glued on the tensile and compressive faces of the sample (Simonin *et al.*, 2002) or digital image correlation. The calculation of the stress is then possible, for example if the stress-strain relationship in compression and tension is known (Leplay *et al.*, 2010).

Instrumented indentation

This direct technique is a local measure, allowing the determination of elastic properties in multiphase materials (as for cemented carbides or concrete (Velez *et al.*, 2001)), or in the presence of gradients of properties. It is also largely used in polycrystalline materials and glasses (Lawn, 1998; Rouxel *et al.*, 2010; Molnár *et al.*, 2016) as it enables to get properties from a small samples with no need of a well-controlled geometry. In addition, it can give a series of values on a single sample. Hardness determination by indentation is one of the most popular mechanical characterization method in Material Science. To get access to the elastic modulus, the indentation test must be instrumented, i.e., the load-displacement curve must be recorded during testing (Fig. 4).

In instrumented indentation testing, hardness is defined as the applied load to the projected contact area at maximum load, and elastic modulus can be estimated from the initial slope S of the unloading curve. The theoretical calculation is based on Sneddon work: (Fischer-Cripps, 2004)

$$S = \left(\frac{dP}{dh} \right)_{P_{\max}} = \frac{2\beta}{\sqrt{\pi}} E_r \sqrt{A(h_c)}$$

with P the applied load, h the penetration depth, h_c the contact depth, β a constant value depending of indenter geometry (1 for sphere and 1.012 for the Vickers), A the projected contact area of the tip and E_r the reduced Young's modulus.

The contact depth h_c is determined from the total penetration depth using different methods, such as Oliver & Pharr or Loubet methods (Oliver and Pharr, 1992; Bec *et al.*, 1996). The presence of sinking-in or pile-up around the indent has to be taken into account. Pile-up is usually observed in soft metals and more rarely on ceramics and glasses.

In Oliver & Pharr method, the contact depth h_c is calculated from the relation:

$$h_c = h_{\max} - \varepsilon \frac{P_{\max}}{S}$$

with $\varepsilon = 0.75$ for a Vickers/Berkovich tip and 0.72 for a sphere.

The reduced modulus E_r is determined using the following equation:

$$\frac{1}{E_r} = \frac{1 - \nu^2}{E} + \frac{1 - \nu'^2}{E'}$$

with E and ν are respectively the Young's modulus and Poisson's ratio of the sample. E' and ν' being similar parameters for indenter's material. The values for the tip are usually well known, an assumption must be made on the Poisson's ratio of the tested material to estimate E .

The contact area is determined from the area function of the tip (defined as the projected contact area versus the penetration depth). For tips with a perfect geometry, $A(h_c)$ is calculated from the contact depth according to the following relations:

$$A = \pi a^2 = 2\pi R h_c - \pi h_c^2$$

for a spherical indenter of radius R

$$A = 4h_c^2 \tan^2 \theta = 24.5 h_c^2$$

for a Vickers or a Berkovich indenter.

Tips are usually pyramidal (Vickers and Berkovich being the most popular in instrumented indentation) or spherical. Spheres lead to a progressive setting of the tip / material contact and to a larger contact area at a given penetration depth, and therefore higher loads, as compared to sharp tip. Spherical tests are however more sensible to surface roughness since the penetration depth is lower.

A precise determination of the area function of the tip is necessary. Tests on calibrated fused silica is often used to identify the exact area function. Other corrections (frame compliance, thermal drift...) have to be made. The readers are encouraged to refer to reference books on this subject (Fischer-Cripps, 2004). An ISO standard is dedicated to instrumented indentation testing (ISO-14577, 2015).

Requirements on the sample for instrumented indentation are less conservative than for other mechanical tests, as no well-controlled geometry is needed, but only two flat and parallel surfaces. The surface state of the indented surface is critical as no reliable measurement is possible if the penetration depth is not at least three to five times larger than the root mean square (RMS) roughness (Miller *et al.*, 2008). The applied load must be high enough to avoid surface roughness influence and not too high to limit damage and cracking to ensure an elastic behavior during unloading. Continuous Stiffness Measurement (CSM) mode can be used to estimate the evolution of Young's modulus (and hardness) versus the penetration depth during the test.

Determination of Fracture Strength

A theoretical fracture strength of a perfect monocrystal can be calculated from the knowledge of its interatomic bounds. For cleavage fracture, this theoretical value approaches $E/7$, leading to tensile strength values above 10 GPa. Experimental values of tensile strength in ceramics and glasses are far below the theoretical strength, as the fracture originates from defects present in the material. Defects can be found in volume (related to fabrication: pores, impurities...) or at the surface (mainly related to fabrication and to sample preparation: machining, grinding, polishing). Guides for the fractography analysis are available (Quinn, 2007; EN843-6, 2009). The critical defect size, leading to the failure of a sample, can be calculated with the following formula:

$$a_c = \frac{1}{\pi} \left(\frac{K_{IC}}{\sigma_t} \right)^2$$

with K_{IC} the fracture toughness and σ_t the tensile fracture stress.

The determination of both parameters is therefore critical in the design of materials. For detailed studies on fracture mechanics of ceramics and on the design of ceramic component, specific references are recommended such as (Lawn, 1993; Danzer *et al.*, 2008).

For brittle materials like glasses and ceramics, a strong influence of the loading mode on the fracture strength is noted. The uniaxial compression strength is usually between five to ten times larger than the uniaxial tension strength. The choice of testing method for fracture strength determination is therefore of high importance and depends on the loading conditions in service, including manufacturing and handling. During service life, tension stresses are nearly always present (for example during machining, or due to residual stresses related to temperature gradients during processing or usage). Tension strength is usually the limiting strength for glasses and ceramics and is therefore a critical demand. However, in some applications such as the core of lightweight mineral boards for construction, the main solicitation is compressive.

In the following section, main different strength tests available for ceramics and glasses are listed according to their loading mode (uniform uniaxial loadings, non-uniform uniaxial loadings and multiaxial loadings). General recommendations for testing given in the previous section for the determination of elastic moduli (Section "Direct Methods") are also valid for strength determination. However, no measure of the specimen displacement is needed as fracture stress is calculated from fracture load and geometrical parameters.

The control of the test (either displacement-controlled or load-controlled) is not critical for purely elastic brittle material, as the fracture load is then easily identified as a drop in load at failure. This may be different for materials showing nonlinear behavior (for example due to local damage or plasticity). In that case, load-control testing is preferred to precisely determine the load at failure.

Fig. 5 Uniaxial tension testing: eccentricity e and misalignment α .

Uniform Tests

In such tests, the stress field is theoretically homogeneous in the sample, leading to a straightforward determination of the fracture strength, defined as the ratio of the fracture load to the cross-section area. However, imperfections during testing may influence the measured strength.

Uniaxial tension

It is the most adapted test to measure the tensile strength, however it is not commonly carried out on brittle materials due to the difficulty to avoid stress concentrations and secondary bending. Any imperfection during testing will tend to decrease the measured tensile strength.

Two main sources of imperfection in the tensile test are misalignment and eccentricity, as illustrated in [Fig. 5](#). To limit the misalignment two options exist, either using rigid fixations that should be perfectly aligned, or using equipment's allowing rotations (using universal/cardan joints) to ensure the best alignment. For sample gripping, two main options exist: either with glued tabs to limit damage in the holding part of the specimens, or direct mounting with half-shells to grip cylindrical specimens ([Hild et al., 1992](#)).

The use of samples with a perfectly controlled shape, usually dog-bone shaped, with a circular or a prismatic cross section, is also necessary. Samples with large cross section reduces eccentricity and facilitates the adjustment of grips ([Munz and Fett, 1999](#)). The zone with reduced cross-section has usually a length of 10 times the diameters for cylinders and at least 10 times the thickness for samples with prismatic cross section.

Strain gages glued on both sides of a flat rectangular tensile specimen enable to check the presence of a potential bending moment during testing ([Noguchi et al., 1990](#)). A correction of the fracture strength calculation is then possible, taking into account supplementary flexion ([Christ and Swanson, 1976](#); [Munz and Fett, 1999](#)). Digital image correlation monitoring during testing can also help to quantify test imperfections ([Leplay et al., 2010](#); [Bouterf et al., 2015](#)).

Uniaxial tension testing is usually performed on materials showing a non-linear behavior in tension such as concrete ([van Mier and van Vliet, 2002](#)) and thermostructural composites (ceramic matrix composites) ([Dalmaz et al., 1998](#)), as bending tests are usually preferred to estimate tensile strength for perfectly elastic materials up to failure.

Uniaxial compression

Under such loading conditions, ceramic samples can sustain very high stresses levels (several GPa) and therefore very high loads. Calculation of strength is straightforward as the ratio of fracture strength on the cross-section area. As noted for Young's modulus determination, compression testing seems easier to carry out than tension testing as the sample does not need to be gripped. This is only partially true as the friction at the interface between loading platens and sample can largely affect the fracture strength by generating unwanted local tension stresses. A possible flexion can also appear when testing rigid materials due to non-parallel

Fig. 6 Uniaxial compression testing, schematic representation of the influence of sample surface quality.

Fig. 7 Different fracture mode in uniaxial compression.

loading surfaces. The use of freely rotating upper platen (ball joint) is recommended, especially for all samples with non-perfectly parallel surfaces. It is also possible to surface treat the sample with a compliant material (wax, sulfur) to reduce friction, as commonly done in concrete. [Fig. 6](#) illustrates the influence of a non-perfect parallelism on load-displacement curve in uniaxial compression.

Sample geometry has an influence on the measured strength, and it is known in concrete testing that for a similar volume, testing cubes lead to higher strength than cylinders of 20% typically. Cylindrical samples, with an axisymmetric geometry, are preferred for uniaxial compression testing. A minimum aspect ratio (ratio of height on diameter) of two is needed to fully develop shear bands when testing frictional materials. The aspect ratio of samples should be below three to limit the risk of buckling during test. Therefore, cylinders with aspect ratios varying from two to three are most commonly used.

The observed fracture mode depends on the materials tested (see [Fig. 7](#)):

- For dense ceramics and glasses, brittle failure is noted with cracks oriented along solicitation direction (maximum tensile stresses) ([Sammis and Ashby, 1986](#)),
- For highly porous materials, there is a transition from brittle to cellular behavior with increasing porosity, with a progressive shortening of the sample by collapse of horizontal layers ([Meille et al., 2012](#)),
- For frictional materials (concrete, porous ceramics), shear induced damage is observed, with formation of shear bands with extensive cracking at 45° from the loading direction.

In scientific papers, it is recommended to show a typical experimental stress-strain curve and to describe the fracture mode observed in uniaxial compression test. A precise description of the surface preparation of the samples (polishing, control of the parallelism between top and bottom surfaces, presence of a compliant layer) is also necessary, as it may impact the fracture strength.

Non-Uniform Tests

Bending or flexion test

Bending test is by very far the mostly used testing method to determine the tensile strength of brittle materials, as the direct tension tests are difficult to carry out properly. Note that fracture strength as determined in bending tests can lead to different values than direct tensile tests (see Section "Parameters Influencing Strength").

Bending loading favors fracture from the sample surface loaded in tension (usually the bottom face, as illustrated in Fig. 3), highlighting the influence of surface defects. Note that in uniform tests, the location of defects (surface or bulk) does not affect the probability of failure of the sample. Flexion tests are usually under 3 points or 4 points configurations, with respectively one and two upper rollers. For fracture stress determination, 4 point bending is preferred as the zone between the upper rollers is submitted to the same stress state (constant bending moment). This latter test is therefore more adapted to the influence of the defect distribution on the fracture strength.

Experimental issues still exist in bending tests, especially in the case of a sample with non-parallel top and bottom surfaces. It is recommended to use a test equipment with a freely rotating upper platen. Additional imperfections during testing may arise from large deflection (change in the distance between sample/rollers contact points), from wrong span positioning, and from contact stresses at the loading points. For a detailed analysis of the influence of initial sample curvature, wrong spans, eccentric loading, and friction, the readers are recommended to refer to (Quinn and Morrell, 1991; EN843-1, 2007).

The ratio of the distance between the two lower rollers to the sample height, referred as slenderness, is usually above 8 to limit the influence of shear stresses influence. This is critical for Young's modulus determination as mentioned in the previous section, but shear stresses might also induce fracture at mid-height of the sample (where the shear stresses are maximal) in the case of specimens with weak interfaces (case of anisotropic materials: composites, laminates).

A large majority of bending tests are carried out on bars. The control of the surfaces parallelism is critical, chamfrains are also preferred to limit stress concentrations at the edges of the samples. The formula for determination of the tensile strength for bars is given by:

$$\sigma = \frac{3P(l_{\text{lower}} - l_{\text{upper}})}{2bh^2}$$

with P applied load, b sample width, h sample height, l_{lower} and l_{upper} the distances between lower and upper rollers respectively. In case of 3 point bending, the formula is valid with $l_{\text{upper}} = 0$.

Flexural tests on rods also exist, as processing cylindrical specimens may be convenient, as for example with glass rods, porcelains, or catalyst supports. A particular attention to the contacts stresses at the loading points is necessary, even with the use of curved rollers (Mitchell *et al.*, 2009). The fracture stress for cylindrical specimens is given by:

$$\sigma = \frac{8P(l_{\text{lower}} - l_{\text{upper}})}{\pi D^3}$$

with D sample diameter. The equation is valid for 3-point bending with $l_{\text{upper}} = 0$.

In any loading configuration, it is necessary to check the location of the failure section in the sample. It should lie between the two upper rollers for 4 points bending. If the fracture occurs always below the same upper roller, the testing equipment leads certainly not to the same applied load for the two upper rollers (it should be $P/2$ for both rollers). For 3 point bending, if fracture is noted at a distance from the upper roller, the calculation of the fracture stress should be corrected. This can be easily done as the tensile stress in the bottom face of the sample varies linearly from a maximum value below the upper roller to a zero value at the contact line with the lower rollers. Cracks initiation at the contact zone with rollers should also be carefully checked.

In case on non-purely elastic behavior (non-symmetry between tension and compression stresses due to microcracks propagation (Bruno *et al.*, 2012), tests at high temperature with viscous effect (Leplay *et al.*, 2012), or elasto-plastic behavior associated to phase transformation (Chevalier *et al.*, 2019)), the formulas to calculate the fracture strength are no longer valid. The knowledge of the stress repartition along the thickness of the sample is necessary to estimate the tensile stress in the specimen. Assumption on the compression and on the tension behavior are then necessary. Bending testing is therefore not always the preferred characterization method for tensile strength determination, and uniaxial tension testing may be more relevant.

Multiaxial Tests Used to Determine Tensile Strength

Brazilian test (diametral compression)

This test is an alternative option to estimate the tensile fracture strength of brittle materials using a uniaxial compressive loading on cylindrical specimens. It has been initially developed to determine the tensile strength of concrete and later adapted to ceramics (Wright, 1955; Marion and Johnstone, 1977; Munz and Fett, 1999). It is a standard test for tensile strength determination on cylindrical catalyst supports (ASTM-D4179, 2003; ASTM-D6175, 2003). The sample is set horizontally with loading direction along the diameter of the sample (no need to grip the sample, see Fig. 8(a)). A linear contact between sample and upper and lower platens is supposed, leading to very high contact stresses. A compliant material (small piece of cardboard or of lightweight wood) is often used at the contact between sample and platens. Initiation of fracture occurs by the propagation of a vertical crack at the center of the section of the sample. The stress repartition is not homogeneous, with axial stress (σ_1 in Fig. 7) varying from

Fig. 8 (a) Illustration of the diametral compression test (Brazilian test) with evolution of K_1 and K_2 constants along the height of the sample and (b) geometrical parameter and illustration of the C-sphere test, from Supancic *et al.* Reproduced from Supancic, P., *et al.*, 2009. A new test to determine the tensile strength of brittle balls – The notched ball test. Journal of the European Ceramic Society 29 (12), 2447–2459. doi:10.1016/j.jeurceramsoc.2009.02.018.

compressive (at the contact points) to tensile, whereas transverse stresses (σ_2) are always compressive and are minimal at mi-height. General formulas for σ_1 and σ_2 are:

$$\sigma_1 = K_1 \cdot \frac{2}{\pi} \cdot \frac{P}{Dl}$$

$$\sigma_2 = K_2 \cdot \frac{2}{\pi} \cdot \frac{P}{Dl}$$

with P applied load, D sample diameter, l sample length, K_1 and K_2 constants.

On Fig. 8(a), the evolution of K_1 and K_2 is plotted along the height of the cylinder. Values at mi-height of the section, where the crack is initiated, lead to the following formulas for σ_1 (tensile stress, used for the tensile fracture strength calculation in brittle materials) and σ_2 (compressive stress):

$$\sigma_1 = \frac{2P}{\pi Dl}$$

$$\sigma_2 = \frac{-6P}{\pi Dl}$$

This test should not be used in case of large damage or densification in the sample near the contact lines as this would modify the calculated stress fields.

Fig. 9 (a) Schematic representation of ring on ring test with associated geometrical parameters, (b) illustration of a ball on 3 balls test (MATEIS, INSA Lyon).

C-Sphere test

This test has been initially developed to estimate the tensile strength of spherical samples (for example for balls used in ball-bearings). A slot is machined in a spherical sample and a uniaxial compression load is applied perpendicularly to the direction of the slot (see Fig. 8(b)). This solicitation is particularly adapted to test the influence of surface defects in spherical specimens, with a relative simple sample preparation. Test could be carried out on unnotched balls but the fracture occurs then at very high loads and any fractography of the sample is then impossible due to the disintegration of the sample after test (Wereszczak *et al.*, 2007). More recent work (Supancic *et al.*, 2009) has widened the use of this test, also referred as the notched ball test, considering variable notch shape and ball size. Note that a positioning aid to maintain the horizontal position of the notch during testing is helpful. The determination of tensile fracture in a C-sphere stress is done through a careful finite element (FE) analysis. The fracture stress can be computed with the following analytical formula:

$$\sigma = f_N \frac{6P}{h^2}$$

with P the applied load, h the ligament length and f_N a shape factor, depending on the relative notch length and width, the relative radius at the notch base, and the Poisson's ratio of the material, given in Supancic *et al.* (2009). A C-ring test also exists for determining strength for ring or tube-shaped components (EN843-7, 2007).

Biaxial bending

Biaxial bending is commonly used for tensile strength determination, due to the relative easiness to produce disk-shaped samples. Disks testing also limits cutting operation after pressing and sintering of ceramics as compared to bars testing. A major advantage of this procedure is to limit the influence of the edges of the sample, where machining may generate additional flaws, on contrary to 3 or 4 point bending tests. Biaxial tests are also more relevant for characterizing strength in the presence of residual thermal stresses, mostly biaxial in service application of ceramics components.

In a *ring-on-ring test*, a disk is supported on a ring and loaded by a concentric ring of smaller diameter, leading to a curvature of the sample and to biaxial bending (see Fig. 9(a)). The fracture strength is calculated as the maximum stress in the surface in tension (the surface in contact with the larger ring, usually the bottom face). In this test, radial and tangential stresses are identical (biaxial stress state), leading to a solicitation of the surface defects whatever their orientation. The determination of radial and tangential stresses in the tensile-loaded surface is given in (ISO-6474, 2011; ASTM-C1499, 2013) for $r < r_1$ where the stresses are maximum (expressions for $r > r_1$ are detailed in Munz and Fett (1999)):

$$\sigma_i = \frac{3P}{2\pi t^2} \left[(1 + \nu) \ln \left(\frac{r_2}{r_1} \right) + (1 - \nu) \left(\frac{r_2^2 - r_1^2}{2r_3^2} \right) \right]$$

i stands for radial and tangential directions

with P applied load, t sample thickness, r_1 loading ring radius, r_2 supporting ring radius, r_3 sample radius, and ν Poisson's ratio.

The equation is considered as valid if the disks are thin enough to limit shear stresses. It is usually recommended to have a support ring diameter at least 10 times the sample thickness. The failure of the sample should initiate from the tensile surface, where the formula is valid. Edge initiated failure should be removed from the analysis.

The limitation of the ring-on-ring test lies mainly in the need of a sample with parallel and flat surfaces, and with possible friction at the ring/sample contact line. The use of compliant layers to reduce friction effect is often made, especially for non-flat specimens.

Several adaptations to the ring on ring test have been proposed (ball on ring, ball on ring of balls, piston on three balls (Börger *et al.*, 2002; ISO-6872, 2015)), mainly to reduce friction effect and to be more tolerant to non-perfect parallel surfaces.

The *ball-on-three-balls (B3B) test* (Shetty *et al.*, 1980) a popular method to characterize the strength of ceramic components, for example on as sintered samples for production control. It has also been shown as particularly adapted to small specimens (Danzer *et al.*, 2007). A loading ball touches the disk-shape sample at the center of its top surface and the three supporting balls touch the disk on three points situated on a circle of radius R_a of its bottom surface (Fig. 9(b)). The calculation of the tensile stress is more difficult as compared to the ring-on-ring test due to the loss of axial symmetry, and extensive FE analysis is necessary. Analytic formulas are available to estimate the biaxial tensile stresses (Börger *et al.*, 2004):

$$\sigma = f \frac{P}{t^2}$$

with P the applied load, t the disk thickness and f a shape factor given by Börger *et al.* (2002), depending on R and t radius and thickness of the disk respectively, R_a radius of the circle defined by the contact points of three supporting balls, and constants varying with the Poisson's ratio of the tested material.

The formula is considered as valid for disk with thickness to radius ratios ranging from 0.05 to 0.6, limiting the risk of disk buckling (if too thin) and the risk of high contact loads at the ball / disk contact. Influence of test imperfections are discussed in Börger *et al.* (2004). The testing equipment should ensure a precise centering of loading and supporting spheres as well as allow ball rotation to reduce friction influence.

The *three balls-on-three balls (3B3B) test* has been developed from the B3B test to reduce the influence of loading stress spots and to increase the surface area tested (Fett *et al.*, 2007). Three loading balls and three supporting balls are used with two different configurations: loading and supporting spheres "in line", i.e., sphere centers located at the same polar angle, or loading or supporting spheres rotated by 60° .

For the "in line" configuration, with $R/R_1 = 2.25$ and $R_2/R_1 = 2$, R_1 being the radius of the loading sphere location circle and R_2 the radius of the supporting sphere location circle, the maximal tensile stress can be estimated by Fett *et al.* (2007):

$$\sigma = \frac{P}{t^2} \left(0.656 \left(\frac{t}{R_1} \right)^{-0.196} + 0.274 \left(\frac{t}{R_1} \right)^{-0.448} \nu \right)$$

with P applied load, t sample thickness, ν Poisson's ratio, and R_1 radius of the loading sphere location circle.

As the surface submitted to tensile stresses is larger than in B3B test, the average fracture strength as determined by 3B3B test is usually smaller than with B3B test.

Triaxial testing

It is possible to run triaxial tests on samples with three different principal stresses σ_{11} , σ_{22} , and σ_{33} (see Fig. 1). These are complex tests, rarely done on dense ceramics and glasses, but more common on rocks and soils, in order to determine a fracture criterion valid for any stress state. Triaxial tests were run on ceramics using internally pressurized tubes loaded axially in tension or compression (Ikeda and Igaki, 1984). Purely hydrostatic compression tests with three identical principal stresses, using either three manifolds, or pressurized fluid, or diamond anvil cells, lead to densification with absence of fracture, see for example (Keryvin *et al.*, 2014) on glass and (Bouterf, 2014) on porous ceramics.

Towards Small Scale Testing

Testing small samples is an increasing demand, as for example for electro ceramics components, for samples processed by complex methods (freeze-casting, magnetic assisted casting with a limited maximum size), or for explants of bio-ceramics or bio-glasses. A straightforward method for small scale testing is to miniaturize standard tests, for example the 4 points bending test (Lube *et al.*, 1997). The main limitation is this size reduction seems to be the influence of the contact stresses at the sample – roller interface. Using ceramic cylindrical rollers, the minimum distance between lower rollers is approximately 10 mm, corresponding to a typical sample size of $2 \times 2 \times 12 \text{ mm}^3$. A special care has to be brought to limit the roughness of samples with respect to roller diameter, the use of free rollers can also help to limit friction influence (Lube *et al.*, 1997). The B3B test is also well adapted for testing small samples.

To characterize the fracture strength at a smaller scale, micromechanics tests should be used on micro-specimens, usually in bending on cantilever beams or in compression on micropillars. Several approaches exist to fabricate such samples, such as FIB milling (Dehm *et al.*, 2018; Henry *et al.*, 2019a,b) (see Fig. 10), lithography (Gravier *et al.*, 2009), or micro electroerosion (Modica *et al.*, 2017). The typical samples dimensions are at the micron scale, ranging from 1 to 100 μm . Micromechanical testing offers the possibility to test inside grains, at grain boundaries, of thin layers. Strength values are usually very high as compared to standard specimen, typically of several GPa in tension, this being related to the small specimen size (Norton *et al.*, 2015; Henry *et al.*, 2019a,b).

Small scale testing is however highly demanding and requires electronic microscopy imaging for a precise measurement of geometrical parameters, numerical analysis to model the real loading conditions and the sample exact dimensions, and testing with micro or nanoindenters, ideally in situ. FIB milling may lead to ion implantation and amorphization, possibly modifying the

mechanical properties. The release of existing residual stresses during machining may also affect the mechanical parameters (Norton *et al.*, 2015). It is particularly the case for notch milling for testing fracture toughness, and less critical for fracture strength determination on un-notched samples.

Parameters Influencing Strength

Influence of sample preparation (polishing, annealing)

Sample preparation has a strong influence on strength, which appears to be rather logical as in many testing configurations (see bending), fracture initiates at the surface, where the tensile stresses are highest. A large influence of the presence of defects, of the surface roughness, and of residual stresses on the fracture strength and on its experimental distribution is found (Table 1). The sample preparation protocol before testing is therefore critical. One should choose sample preparation to have the closest sample state as compared to the in service conditions.

Test environment (temperature, presence of water)

At room temperature, fracture strength may be impacted by presence of water. Adsorbed water at the surface of samples and in the volume of porous samples reduces ionic and secondary (Van der Waals) bonds, and therefore decreases strength. This effect is largely referenced for ionic solids (gypsum, NaCl), glasses, and oxide ceramics, with possible slow crack growth due to stress corrosion (Wiederhorn, 1969, 1974). Local dissolution is also possible for ionic solids. It is recommended to control the storage conditions of samples, especially for materials with a high specific surface, as well as to control the temperature and relative humidity in the test rooms (or at least to mention the temperature and relative humidity in the test room in scientific papers).

High temperature testing of ceramics is critical as retaining high strength and rigidity at high temperature is an intrinsic characteristics of this class of materials. This can be done in oven with resistive heating and using magnetic susceptors heated by induction. A good control of the homogeneity of the temperature of the sample is necessary. The displacement measure for rigidity determination may be done with high temperature extensometers or using DIC. For glasses and ceramics, non-linear behavior is often more pronounced at high temperature than at room temperature due to viscous flow, leading to a possible anisotropy in tension-compression behavior. Therefore caution is required in the analysis of bending tests as the neutral axis may not be at mid-height of the sample.

Both water absorption and high temperature favor time-dependent effects in materials. Thus, strain rate, or stress rate, during testing may have an influence of the fracture strength (strength increases with the strain-rate), and therefore needs to be mentioned in the papers.

Statistical Analysis/Size Effect

As ceramics and glasses are brittle materials, their fracture strength is largely affected by the presence of defects and can show an important scatter. It is therefore necessary to characterize the strength in terms of probability of failure using a statistical analysis. This is not the objective of this chapter as many reference documents exist. Weibull or Gaussian distribution functions can be used for that purpose (Lu *et al.*, 2002; Gorjan and Ambrožič, 2012). The most largely used function is Weibull, based on the weakest link theory, and well adapted to describe the fracture of brittle materials. The identification of the Weibull parameters (σ_0 and m) is preferably done with the maximum likelihood method (EN843–5, 2007; Davies, 2017).

The influence of the sample size on strength, linked to the statistical distribution of defects, is important in brittle materials. The volume under tensile stresses has a strong influence on the fracture strength, the larger the volume, the higher the probability to find a critical defect and therefore the lower the strength. As already mentioned, the tensile stress repartition in a specimen is also dependent on the test used (uniaxial tension, uniaxial or multiaxial flexion). The quantification of the sample size effect for standard test methods is based on the calculation of an equivalent volume, or an equivalent surface, depending on whether the fracture initiates from volume or surface flaws. The equivalent volume V_E (or equivalent surface S_E) is that of a uniaxial tensile specimen which, when subjected to a tensile stress σ_m , has the same probability of fracture as a specimen of volume V (surface S) stressed at σ_m in the test method considered (Quinn and Quinn, 2010). Formulas to estimate the influence of the sample size for standard testing geometries (such as 3 point and 4 point bending, biaxial bending, C-sphere test) are available in literature (Quinn, 2003; Rödel *et al.*, 2009; Supancic *et al.*, 2009). For multiaxial tests, the principle of independent action is often considered to perform the calculation of the equivalent volume.

As limitations, the Weibull distribution was found not to be valid to describe the sample size effect for very small samples (Danzer, 2006), as well as for porous materials (Lu, Danzer and Fischer, 2004). Size effects also exists in compression (Bazant, 1997). As a general trend, the larger the specimen volume for a given loading configuration, the higher the stored elastic energy before failure, and the more brittle the behavior.

Conclusion

For a proper experimental determination of Young's modulus and fracture strength, a relevant testing method first need to be chosen. As many experimental methods exist, the choice depends on the application targeted for the material, on its environment conditions in service (temperature, relative humidity), and also on the capability to produce samples with a controlled geometry. One critical question to be asked before choosing the testing method is: what do I want to measure? Testing a material in the most representative conditions to be relevant with respect to the application is certainly an important point to keep in mind for that purpose.

Please note that this chapter does not present an exhaustive list of testing methods for brittle materials, but the mainly used ones. Many other exists or will be developed. Below are some general recommendations:

- (1) Young's modulus is an intrinsic value for a material, averaging the contributions of its microstructural features. Two main groups of measurement techniques exist: vibration (dynamic) or mechanical testing (quasi-static), also referred as direct methods. Dynamic methods are more accurate than direct testing. For static tests, a precise measurement of displacement is needed when testing rigid materials. The use of extensometers is often necessary, digital image correlation can also be well suited to characterize the displacement field in the specimens.
- (2) Fracture strength is not an intrinsic material property, as it largely depends on the loading mode and on the testing method. The stress field in the sample tends to favor fracture either from the surface or from the whole volume of the sample. Special care to the control of test protocol as well as to the assumptions made to calculate the stress is needed. As sample size, surface preparation, and environment conditions have a strong influence of the fracture strength, it is recommended to test samples with a size and a surface state representative of the service conditions, in a relevant environment.

As a final remark, in addition to the description of the test method in scientific papers, authors should also give precise information on sample size and surface preparation, on environment conditions during storage and testing. Showing typical load displacement curves with a description of the observed fracture mode is also necessary. This could be possibly done in supplementary information associated to scientific articles.

Fracture Toughness Measurement

Tanja Lube, Department of Materials Science, University of Leoben, Leoben, Austria

Introduction

As structural materials, ceramics are characterized by their brittle failure behavior. The material property that is used as a measure to quantify this brittleness is the fracture toughness. Even though ceramics have a much lower fracture toughness than most metals, some are tougher and easier to use in demanding applications and some are more brittle and prone to failure. As they are intended to be used in load bearing applications, the fracture toughness – although it is usually not a design quantity – will be a guide for choosing appropriate materials. Increasing toughness is a prior objective in materials development, fracture toughness is a measure in material qualifications, material manufacturers want to give numbers in their data sheets. Apart from dictating the strength of a part, fracture toughness is also a relevant material property in many loading situations where ceramics are preferentially used, e.g., in wear situations or environments with high and/or changing temperatures.

In this chapter the basics behind the concept of the fracture toughness will be briefly outlined, standardized test methods will be introduced and it will be shown why the measurement of fracture toughness of ceramics is not straight forward. Standardized methods will be described and discussed in terms of material aspects, comparability across materials and methods and practical issues. Using recent examples, it will be shown how the concepts behind standardized methods have recently been applied to non-standardized specimen geometries or even components. Finally, a section will briefly discuss the use of indentation cracks for the investigation of fracture properties of ceramics.

Basic Principles

Linear Elastic Fracture Mechanics

Under applied stress, failure of ceramics is caused by small discontinuities in the volume or at the surface of components (Danzer *et al.*, 2008). For simplicity, they can be described as small cracks, and are usually termed flaws or defects. In a structure containing cracks, linear elastic fracture mechanics (Gross and Seelig, 2006) can be applied to derive a condition at which propagation of a crack is possible.

First ideas on conditions for crack propagation were described by Griffith (1920). He made a balance for an ideal elastic solid between the energy losses (change in elastic energy, work done by crack propagation) and the energy gains (energy necessary for creating new crack surfaces).

The concept was refined more than 30 years later by Irwin, who proposed the concept of linear elastic fracture mechanics (Irwin, 1958). In his theory all involved energy changes are strictly proportional to the change in crack surface. The strain energy release rate, G , describes all energy losses (elastic energies and work) and the critical strain energy release rate G_c is equal to the energy necessary to create the new fracture surface. Unstable fracture occurs if the energy losses exceed the gain in fracture energy:

$$G \geq G_c \quad (1)$$

For plane stress conditions and for mode-I loading it holds (Ashby and Jones, 1980):

$$G = K^2/E \quad (2)$$

with the stress intensity factor K

$$K = \sigma Y \sqrt{\pi a} \quad (3)$$

The critical strain energy release rate is related to the fracture toughness K_{Ic} by

$$G_c = K_{Ic}^2/E \quad (4)$$

For plane-strain conditions and mode I loading, which are most relevant when testing ceramics, E has to be replaced by $E' = E/(1 - \nu^2)$ (Gross and Seelig, 2006). E is Young's modulus, ν is Poisson's ratio and σ is the stress acting normal to the prospective crack plane in the un-cracked body. Y is a geometric factor, which takes the geometry of the crack, specimen and stress field into account. With this notation the well-known Griffith/Irwin criterion for brittle fracture can be defined:

$$K \geq K_{Ic} \quad (5)$$

In crack-opening mode, fracture occurs if the stress intensity at the tip of a crack with size a reaches the critical stress intensity K_{Ic} . This gives the relation between fracture stress σ_f , fracture toughness K_{Ic} and the size of the failure causing defect a :

$$\sigma_f Y \sqrt{\pi a} = K_{Ic} \quad (6)$$

Note that the above equations were derived for fast running cracks. Eq. (6) is the connection between the material property fracture toughness, the defect size, which is to a certain extent controllable through processing, and the strength, which is the actual design goal for components.

Microstructure and Environmental Effects on Crack Growth

The principles of linear fracture mechanics were derived for a continuum containing a crack with smooth, planar faces that cannot transfer forces. The fracture toughness is assumed to be independent of crack length. Ceramic materials deviate from this model in various ways: they consist of grains, cracks may propagate inter- or transgranularly leaving behind a more or less rough surface, friction may be present between crack faces, phase transformations may take place in the stress field ahead of a crack tip. This is the playground of materials development with the goal to enhance the fracture toughness of a material (Becher, 1991). Crack faces that cannot be separated easily due to bridging elements like coarse grains, whiskers or second phase particles result in an increasing resistance against crack propagation as the crack advances. A phase transformation in front of a crack that results in particles with an increased volume shields the crack tip from applied stresses and also increases the fracture toughness during crack growth. In such cases, where a material exhibits so-called R-curve behavior, the fracture toughness depends on the extent of advance which a crack has undergone before becoming critical. This amount differs for the test methods described here. An assessment, how R-curve behavior influences the measured fracture toughness value can be found in the Section "Standardized methods and R-curves". The measurement of fracture toughness as a function of crack advance poses additional challenges to the measurement technology, i.e., simultaneous capturing of crack advance and load during stable crack extension and requires specific test procedures. For a detailed treatise on this topic, the reader is referred to the paper by Munz (2007).

Ceramics, especially oxide ceramics, glasses and silicate-containing materials, are susceptible to environmentally assisted crack growth (Munz and Fett, 1999) which takes place at stress intensities below the critical one and is therefore called sub-critical crack growth (SCCG). It is chemically triggered (Michalske and Freiman, 1983) and/or thermally activated (Schoeck, 1990) and is extremely difficult to avoid. Depending on the experimental conditions it precedes every failure to a certain amount, the lower the stressing rate, the more. Consequently, the strength will be low when measured with a small stressing rate (long test duration) and high when measured with a high stressing rate (fast tests). Only in few ceramics the amount a crack has grown by this mechanism can be distinguished by fractography from the residual fast fracture surface (Swab and Quinn, 1998; Quinn, 2016). This has led to the conclusion that in ceramics the true critical stress intensity factor has to be the one for fast fracture.

R-Curve behavior and SCCG can lead to similar features in quantities that are acquired during a fracture mechanical test, e.g., load-displacement curves, so that they cannot be discerned. For a correct interpretation of fracture toughness test results or even the choice of a suitable testing method for a given material it is necessary to know at least if either of them may be present and how it may have influenced the test result.

Standardized Methods for the Measurement of Fracture Toughness of Ceramics

Eq. (6) provides a way to measure fracture toughness. If we have a crack with known size and shape fractured by a measured applied stress and know the geometry factor Y , the fracture toughness K_{Ic} can readily be computed. As for all mechanical testing procedures, care has to be taken, that the reality meets the fracture mechanical model, which is used to evaluate the test, as close as possible. Therefore, mandatory conditions for rigorous fracture toughness measurement are thus (Quinn and Salem, 2003; Morrell, 2006):

- (1) Fracture by fast crack propagation of,
- (2) A well defined crack in,
- (3) A well defined stress field, for which,
- (4) A well defined geometry factor Y is known.

Ideas how specimens and procedures that fulfill these conditions can be implemented have been laid down for metals in ASTM E399 (2017). Unfortunately, these are not applicable to ceramics for several reasons.

- (1) Ceramics are difficult and expensive to machine. It is relatively easy to grind pieces with flat faces, but it is difficult to drill holes or prepare cylinders.
- (2) Fatigue pre-cracking as suggested for metals does not work well for ceramics.
- (3) In many cases, only small material quantities are available for testing. Properties of ceramics depend on processing details. In many cases specimens have to be manufactured out of components.
- (4) The process zone in ceramics is small, so that the condition for small scale yielding also fulfilled for small specimens.

As a consequence, most standardized methods for fracture toughness measurement of ceramics use prismatic bars with a cross section of $W = 4 \text{ mm}$ and $b = 3 \text{ mm}$ and a length of approximately 45 mm which are flexure loaded in 4- or 3-point bending. ASTM C1421 (2018) allows for alternative dimensions for Chevron-notched bars. Pre-cracks or suitable notches are introduced into the prospective tensile surface of the bars by various methods. An overview of loading configuration, specimen dimensions and pre-crack shapes is given in Table 1, typical fracture surfaces are shown in Fig. 1.

Single-Edge Pre-Cracked Beam (SEPB) Method

For the single edge pre-cracked beam (SEPB) method which is standardized in ISO 15732 (2003) and ASTM C1421 (2018), a straight-through pre-crack with a relative depth a/W of $0.35 < a/W < 0.6$ is introduced. The specimen is then fractured in bending

Table 1 Overview of standardized specimens and loading geometries. In the leftmost column, the sketches of specimen cross-sections with the pre-crack and its configuration at fracture indicated in gray are shown. The numbers give the dimensions W and b in mm. The two other columns indicate the allowed loading configurations. L ... specimen length, 4P- x/y ... 4-point bending with support span x mm and loading span y mm, 3P- x mm ... 3-point bending with x mm support span.

Method	ISO, EN ISO	ASTM C1421

with a rather fast loading rate in order to determine σ_f . The fracture test is generally conducted in a way that promotes unstable crack extension. The length of the pre-crack a is measured on the fracture surface, see Fig. 1(a). Specimens with pre-cracks of excessive uneven length or with pre-cracks that tilt or twist away from the ideal plane too much have to be rejected according to criteria specified in the standards.

The crucial point in this method is the introduction of the pre-crack. It is supposed to be driven into the specimen using indentation cracks or a shallow notch or a scratch as starter by a bridge-loading procedure, cf. Fig. 2. The gap in the upper block (the “bridge”) introduces a small tensile stress at the tip of the indentation starter cracks or the scratch. This leads to a pop-in of a longer crack, which is stopped by the overall compressive stress in the bar. There is no means to control the length of the pre-crack. Problems in generation of the pre-crack may occur in transformation toughened ceramics. In front of the indentation starter cracks or scratch a zone with compressive residual stresses may develop which inhibits the pop-in of the pre-crack. This is often expressed by extremely high loads that are necessary to achieve the pop-in. For tougher ceramics ($K_{Ic} > 4 \text{ MPam}^{0.5}$), the pre-cracking requires loads in the order of 8 kN to 25 kN (ISO 15732, 2003) while for the fracture test of the pre-cracked specimen itself, fracture loads are usually only 30 N to 150 N. In order to perform pre-cracking and the subsequent fracture test, two load cells with different maximum load range or even two different testing machines will have to be used to achieve the required accuracy of $\pm 1\%$ in force measurement.

Fig. 2 Schematic of a 'bridge' device to obtain pre-cracks in SEPB specimens.

Surface Crack in Flexure (SCF) Method

This method is standardized in [ISO 18756 \(2005\)](#) and [ASTM C1421 \(2018\)](#). In this test a small semi-elliptical pre-crack is introduced into the bend bar using a Knoop indentation made with a load of typically 5 kg to 10 kg. In order to remove the residual stresses which are associated with the hardness imprint, a layer with a thickness of 4.5–5 times the indentation depth has

Fig. 3 Fracture surfaces of bend bars with Knoop indentation cracks impregnated with fluorescent penetration dye. (a) no material was ground off before the fracture test. The dashed line indicates the original specimen surface. (b) a ground-off crack, the dashed line indicates the new specimen surface. The deepest point, at which the maximum stress intensity will act, is indicated by A.

to be gently ground off the indented surface of the bar, see [Fig. 3](#). Then the bar is broken in a conventional 4-point bend test. The fracture toughness is calculated from the fracture stress σ_f of the bar, the crack depth, the surface crack length and the geometrical factor for semi-elliptical cracks derived by [Newman and Raju \(1981\)](#) for a Poisson's ratio of $\nu = 0.3$. The size of the pre-crack is measured on the fracture surface of the broken bar, see [Fig. 1\(b\)](#). In order to facilitate this, it is suggested to introduce the pre-crack with a slight twist or tilt with respect to the prospective fracture plane. While the generation of pre-cracks is straightforward but sometimes fails in transformation toughened materials, the identification of the pre-cracks on the fracture surfaces may be difficult, especially in coarse grained materials. Dye penetration procedures with inks (for light colored ceramics) or fluorescent dyes (for dark materials, [Fig. 3](#)) may facilitate this step.

Knoop indentations do not only generate the desired semi-elliptical surface breaking cracks but also cracks which run parallel to and below the surface – so called lateral cracks. They may be removed by the usual grinding procedure, but in some materials they are located at a depth beyond the ground-off layer ([Lube, 2001](#)). If they remain present in the specimens, the fracture toughness will be overestimated by up to 12% ([Quinn and Salem, 2003](#)). Checking the surface of the ground bars and possibly grinding off more material is a valid countermeasure.

The geometry factor for semi-elliptical surface cracks in a bend bar according to [Newman and Raju \(1981\)](#) depends on the size and shape of the crack and varies along its front and so does consequently the stress intensity. It is assumed that instable fracture starts at the point with the highest stress intensity. In order to satisfy the four prerequisites for good fracture toughness tests, it is desirable to get fracture from the deepest point of the crack front (point A in [Fig. 3\(b\)](#)). This is favored by shallow crack shapes, which in turn are generated by grinding off more material. As it is obvious from [Fig. 3](#), shallow cracks made in this way are no longer strictly semi-elliptical, they are truncated ellipses. This motivated a re-evaluation of the stress intensity factor for small surface cracks which also took into account values for Poisson's ratio different from $\nu = 0.3$. It turned out that a difference of several per cent may exist between the two solutions for specific geometries and Poisson's ratios ([Strobl et al., 2012a, 2018](#)). A study on glasses, where measurements made with the SEPB method and the SCF method were compared, showed that equal results could only be obtained when the new geometry factor for the correct Poisson's ratio was used ([Quinn and Swab, 2017](#)). The new geometry factors are available as fitted functions ([Strobl et al., 2012a, 2018](#)) or through an online tool ([Lehrstuhl für Struktur- und Funktionskeramik, 2020](#)).

Chevron-Notched Beam (CNB) Method

The method is standardized in [EN 14425-3 \(2010\)](#), [ISO 24370 \(2005\)](#), and [ASTM C1421 \(2018\)](#). Besides the preferred chevron shape, ISO 24370 allows for alternative geometries with certain restrictions, ASTM C1421 is even more flexible with three different possible cross sections and two different chevron shapes allowed for standard bend bars with a cross section of $3 \text{ mm} \times 4 \text{ mm}$. For this test method it is not necessary to produce a proper pre-crack. Instead, the bar is notched in a way that a chevron shaped ligament remains intact, [Fig. 1\(c\)](#). Upon loading a sharp crack starts to grow from the tip of the chevron. During further loading this cracks first grows stably because the cracked area gets disproportionately larger. During this crack growth the geometry factor for the crack decreases with increasing crack length. When it reaches a minimum, instable fracture of the specimen occurs. The fracture toughness is calculated from the specimen dimensions, the load at fracture and the minimal geometry factor which depends on the chevron geometry. No measurement of the crack length is necessary, but the existence of the stable crack growth has to be assured. Tests are only valid if the load-displacement-, load-time- or load-backface strain-plots recorded during the test show a behavior like to one depicted in [Fig. 4\(a\)](#) and [\(b\)](#). In [Fig. 4\(a\)](#), the deviation from linearity at P_i indicates stable crack growth before unstable fracture. Plots like the one shown in [Fig. 4\(b\)](#) are recorded, if the crack starts at a small overload, then pops in and finally grows stably until final fracture. Note that the pop-in load P_i may also be slightly higher than the final fracture load $P_{\max}$. Tests without any indication of stable crack growth which give plots like the one shown in [Fig. 4\(c\)](#) are invalid.

The preparation of chevron notches which fulfill the tight specifications given in the standards requires some practice and good equipment. Usually two separate cuts with precise depth through the cross section are necessary which have to be

Fig. 4 Typical load-displacement (P - δ) or load-time (P - t) curves obtained during CNB tests. (a) stable crack growth, valid test (b) crack pop-in followed by stable crack growth, valid test, (c) unstable fracture, invalid test.

aligned within a narrow tolerance. The method can be applied to all ceramics because no complications regarding identification of crack lengths are to be expected. In transformation toughened ceramics and in materials with a high Young's modulus it may be difficult to obtain stable crack growth. A stiff testing system where most of the compliance is in the specimen eases the test procedure.

Single-Edge V-Notched (SEVNB) Method

The most recently standardized method is the single-edge V-notched beam method of ISO 23146 (2012). This method resembles the SEPB method in fracture test execution and calculation of the fracture toughness. Instead of the long, sharp pre-crack a slender notch is used. The fracture toughness is calculated from the stress at failure measured in a 3- or 4-point bend test, the depth of the notch and the corresponding geometry factor. The notch should have a relative depth a/W of $0.2 < a/W < 0.3$ and a notch root radius ρ which is smaller than the mean grain size of the tested material but in any case $\rho < 10 \mu\text{m}$. Such notches can be prepared by sharpening a saw cut with a razor blade and $1 \mu\text{m}$ diamond paste. With the use of a reciprocating machine notches can be cut directly into the smooth specimen surface using a coarse diamond grit. In fine grained materials notch root radii of $\rho \approx 2 \mu\text{m}$ can be obtained, see also Fig. 1(d).

Since a notch has a finite root radius the stress concentration at the notch root is always smaller than at a sharp crack with similar length. A higher load will be necessary to fracture the notched specimen. A fracture toughness test conducted with a notch instead of a sharp crack will therefore overestimate the fracture toughness, the more, the bigger the notch root radius is (Nishida *et al.*, 1994; Damani *et al.*, 1996). In order to measure a true value for the fracture toughness with notched specimens it has to be assured that the criterions (i) to (iv) mentioned above are fulfilled, i.e., that the notch behaves like a sharp crack. Model calculations were performed that assumed that a small sharp crack at the root of the notch is present. If the notch root radius is in the order of the crack length or smaller, this configuration behaves like a long sharp crack (Kübler *et al.*, 1999; Fett, 1999). In actual materials such small cracks are assumed to have the size of typical microstructural features (Damani *et al.*, 1996), for example the grain size. This leads to the conclusion that in order to perform a valid fracture toughness test (with only an insignificant overestimation of the true fracture toughness), the notch root radius has to be smaller than the mean grain size of the investigated material. This fact excludes that the method is applied to very fine grained materials or those in which not sharp notch can be made. In the ISO 23146 it is explicitly stated that the method must not be applied to Y-TZP.

In a round robin (Kübler, 1999) it could be shown that the method delivers consistent results in a variety of materials with suitable grain sizes. It is maybe the most robust method for inexperienced users and can be performed with very low scatter.

Comparison of the Standardized Methods

Studies to compare the results obtained with the SEPB, SCF and CNB methods show that they are equivalent for materials that show no R-curve behavior. The SEVNB method has been shown to only slightly overestimate the results (Quinn *et al.*, 2002). The National Institute of Standards and Technology (NIST) in the USA has developed a Standard Reference Material for fracture toughness (SRM 2100) (Quinn *et al.*, 2005) to provide a baseline for users to evaluate their procedures and equipment.

An overview of different aspects of the standardized methods is given in Table 2. It summarizes the experimental requirements, the necessary expertise and the effect that R-curve behavior and sub-critical crack growth as elucidated above may have on the performance of the methods. Another assessment of features of fracture toughness test methods and a guide to test method selection can be found in CEN/TS 14425-1 (2003).

Table 2 Comparison of standardized methods

	SEPB	SCF	CNB	SEVNB
experimental effort	medium to high	high	medium	low to medium
amount of experience needed	medium to high	high	low to medium	low
approximate crack length at fracture	1000–1500 μm	50–150 μm	several hundred μm	$\approx$ grain size
value on R-curve	saturation	increasing part	increasing part - saturation	begin
sensitive to SCCG	little	considerable	yes	possible
possibility to correct for SCCG effects	sometimes	sometimes	no	no
problematic materials	very tough, $K_{Ic} > 6 \text{ MPam}^{0.5}$	coarse grains, very tough (no indentation cracks)	high Young's modulus, transformation toughening	grain size $< 1 \mu\text{m}$, Y-TZP excluded

Fig. 5 R-curves for some ceramic materials and typical critical crack length ranges for standardized fracture toughness test methods. The R-curves are replotted from literature: Si_3N_4 , in-situ platelet reinforced SiC, 2.8Y-TZP and Al_2O_3 . Reproduced from Fünfschilling, S., Fett, T., Oberacker, R., *et al.*, 2010b. Standardized methods and R-curves

The four methods described so far work with distinctly different crack lengths at fracture. As already reported, they give equal numbers for K_{Ic} for fine grained and non-transforming ceramics (flat R-curve materials). The situation is different if materials are tested which show an effect of the crack length on fracture toughness. For such R-curve materials, considerable diverging numbers may be determined with different methods, cp. **Fig. 5**.

Pre-cracks used in the SEPB method are approximately 1000 μm to 1500 μm long. It can be expected, that with such measurements values near the saturation of R-curves will be determined. The SCF method uses rather small cracks in the range of 50 μm to 150 μm . For some materials with steeply rising R-Curves like self-reinforced silicon nitrides (Fünfschilling *et al.*, 2010b), the results will again be near the saturation value, but for other materials which have a more gently rising R-curve, intermediate values may be obtained. A variation of indentation load to produce pre-cracks of different size permits interference of a possible R-curve trend.

During CNB tests the crack grows stably by an unknown amount which depends on the specimen size and chevron shape (Munz and Fett, 1999). It can be expected that CNB results for R-curve-materials are K_R values somewhere in the rising part of the curve. In SEVNB tests it is assumed that instable fracture starts from a small crack with a size approximately equal to the grain size of the investigated material in front of the notch. SEVNB-fracture toughness will thus be near the start of the R-curve (Kübler, 1999).

Standardized methods and sub-critical crack growth

Sub-critical crack growth (SCCG) precedes every fracture to a certain amount and will therefore also influence fracture toughness measurements. It depends on the investigated material and its susceptibility to this behavior and the test method how to deal with this phenomenon.

SEPB tests can be performed with a variety of loading rates, depending on the applied standard procedure. If the test is conducted rather fast, i.e., with fracture occurring within a few seconds, the effect will be small, as shown even for glasses by Quinn *et al.* (Quinn and Swab, 2017). The same behavior can be observed for the SCF method. In some materials there is a chance that SCCG leaves behind a distinctly different fracture surface than instable, fast fracture (Swab and Quinn, 1998). In such cases the amount the pre-crack has grown by SCCG can be added to the pre-crack length when fracture toughness is evaluated. Some standards recommend performing tests at two significantly different loading speeds to gain insight into possible effect of SCCG on the measurement.

Cho *et al.* (2006) showed that generally, the SCF method is more sensitive to SCCG because at the same K the small crack in a SCF-specimen experiences a much larger relative change in crack length and thus in relative K_{Ic} than the long crack in a SEPB specimen.

CNB tests are often performed with low loading rate to facilitate stable crack propagation. This may just as well favor SCCG, which cannot be distinguished from the stable crack growth.

Alternative Pre-Cracking, Methods for Non-Standard Geometries, Components and Recent Developments

More Methods for Introducing Pre-Cracks or Notches

Other – non-standardised – ways to generate pre-cracks for SEPB tests have been reported. These methods have in common that the stress intensity at a given applied load has a maximum at a certain crack length. Crack advance beyond the maximum K requires an increase in load and is thus stable and controllable. This is shown schematically in Fig. 7. Two different ideas have been developed to achieve such K -trends. Fett *et al.* (2000, 2001) suggested to load a short starting notch by two pairs of rollers on each side of the notch as indicated in Fig. 6. The generated contact stress field drives the crack forward, for short crack lengths in an unstable and then in a stable way. Since a quantitative evaluation of the stress field and the geometry factor is provided, it is possible to control the length of the pre-crack by choosing a suitable applied load.

Sglavo *et al.* (Pancheri *et al.*, 1998; Sglavo *et al.*, 1999) suggested to “sandwich” the actual specimen between two metal plates and provided an analytical expression to calculate the stress intensity K as a function of crack length, elastic properties of the sandwich plates, and applied load. Even though simplifications were made in the theoretical analysis, the process is useful to obtain pre-cracks in a controlled way.

As becomes clear from Fig. 7, for both methods it is necessary to know an estimated value of the fracture toughness to predict the crack length at a specific applied load.

Recently studies have been made in which ultra-short pulsed laser ablation using pico- or femto-second lasers were used to obtain notches in various aluminas (Carlton *et al.*, 2016), 3Y-TZP (Turón-Vinas and Anglada, 2014) and silicon nitride (Turón-Vinas and Anglada, 2015). These notches are usually shallow ($\sim 50 \mu\text{m}$) and rather wide but have a small notch root radius. Fracture starts not directly at the notch root but at some kind of material specific damage that is induced in front of the notch. In Y-TZP it was a region of coalescent micro-cracks (Turón-Vinas and Anglada, 2014), in silicon nitride a damaged region containing extremely brittle phases and pores acted as starting crack (Turón-Vinas and Anglada, 2015). It is not clear if these pre-cracks fulfill the mandatory condition of being (ii) well-defined, further work will be necessary to properly assess the effect of the residual damage.

The viability of using focused ion beam milling to produce notches with extremely small tip radii made has been demonstrated by Fünfschilling *et al.* (2010a) on macroscopic specimens. This technique is predominantly used when fracture toughness is

Fig. 6 Schematic of opposite roller loading of a notched bar as suggested by Fett *et al.* Reproduced from Fett, T., Munz, D., Thun, G., 2000. Strength and toughness test devices with opposite roller loading. *Engineering Fracture Mechanics* 29–38.

Fig. 7 Schematic of the trend of K as a function of crack length for opposite roller loading or sandwiched beams. In a material with the fracture toughness K_{Ic} (dashed line), a crack (or notch) with length a_1 will pop-in to length a_2 at a load P_2 . If the load is increased to P_3 and further, the crack will advance stably to the crack lengths given by the intersections of the K -curves with the line for K_{Ic} . Reproduced from Fett, T., Munz, D., Thun, G., 2000. Strength and toughness test devices with opposite roller loading. *Engineering Fracture Mechanics* 29–38. Pancheri, P., Bosetti, P., Dal Maschio, R., Sglavo, V.M., 1998. Production of sharp cracks in ceramic materials by three-point bending of sandwiched specimens. *Engineering Fracture Mechanics* 59, 447–456.

evaluated at the micro-scale using cantilever-beams with dimensions of only a few μm in the course of material investigation on the nano-scale (Cui and Vinci, 2017; Gruber *et al.*, 2018).

Testing of Specific Specimen Geometries or Components

Thin specimens, strips

New applications using very thin ceramics (fuel cells, electronic substrates or particulate filters) have led to the need to measure fracture toughness also on very thin ($0.2 \text{ mm} \leq b \leq 1 \text{ mm}$, $W = 4 \text{ mm}$, $36 \text{ mm} \leq L \leq 45 \text{ mm}$) specimens. In ISO 21113 (2018) variations of the SEPB method and the SEVNB method are standardized for such specimens. The adaptations mainly concern the procedures for pre-cracking, notching and assuring alignment of the specimens during the fracture test. In order to obtain the sharp pre-crack from a starter notch the specimen is glued onto a brass support bar with the tip of the notch slightly below the neutral axis of the support. During bending of the unit, a crack will pop-in. The specimen is then removed from the brass bar and fractured in bending. For the machining of notches, several thin specimens are glued together to form a wider unit which can be notched in a similar way to single bars.

Balls, small disks and plates

For quality control purposes and component development, fracture toughness testing techniques are required which can be applied directly to components, to (very small) specimens cut out of components or to typical specimens used in material development (small disks). Since the microstructure of ceramics sensitively depends on processing conditions, property gradients and inhomogeneity in components may occur (Strobl *et al.*, 2014b). Therefore it is useful to test fracture toughness of the critical areas.

The notched ball test (NBT) has been developed to determine the tensile surface strength of balls used in bearings. A deep, wide notch is cut into the equatorial plane of the ball, which is then compressed at its poles. This leads to a stress field in the surface region of the ball opposite of the root of the notch (Supancic *et al.*, 2009), see Fig. 8(a). This stress field can be used to load a pre-crack, which is made by a Knoop indentation, analogous to the SCF-method. Details like the determination of the geometric function and experimental details have been published (Strobl *et al.*, 2012b, 2014a), Fig. 8. It was shown that fracture toughness can be determined on balls as small as a few millimeters in diameter with an accuracy of a few per cent. This is similar to the typical scatter of fracture toughness results by standardized methods.

Many components appear as small disks or plates. Disc shaped parts are also common in material development. Meaningful strength tests for such of specimens are biaxial tests. For very small disks with diameters down to 2 mm the ball-on-three-balls (B3B) test has been established (Börger *et al.*, 2002, 2004) to complement other biaxial strength tests like the ring-on-ring test (ASTM C1499, 2019) at small dimensions. Again, modifications of the SCF method can be used to measure fracture toughness. This has been elaborated for the B3B-test (Rasche *et al.*, 2014; Strobl *et al.*, 2014c; Lube *et al.*, 2016). The Knoop indentation pre-crack is placed in the center of the specimen on the prospective tensile face, the plastic zone is polished off, Fig. 8(c). The test-piece is then strength tested with the loading ball immediately opposite the pre-crack. A fracture mechanical analysis for determining the geometry factor and the fracture toughness is available. Precise alignment of the pre-crack in the center of the disc is very important, but the technique does enable precise fracture toughness measurements (Belli *et al.*, 2018).

Fig. 8 Application of the SCF-method to components. (a) principle of the notched ball strength test, (b) schematic of a fractured notched ball with an semi-elliptical surface crack, (c) principle of the ball-on-three-balls fracture toughness test. The surface crack is introduced into the tensile side of the disc (the top side in this sketch). Reproduced from Supancic, P., Danzer, R., Witschnig, S., Polaczek, E., Morrell, R., 2009. A new test to determine the tensile strength of brittle balls – The notched ball test. *Journal of the European Ceramic Society* 29, 2447–2459. Strobl, S., Supancic, P., Lube, T., Danzer, R., 2012b. Toughness measurement on ball specimens, Part I: Theoretical analysis. *Journal of the European Ceramic Society* 32, 1163–1173. Strobl, S., Lube, T., Schöppl, O., 2014a. Toughness measurement on ball specimens. Part II: Experimental procedure and measurement uncertainties. *Journal of the European Ceramic Society* 34, 1881–1892. Lube, T., Rasche, S., Nindhia, T.G.T., 2016. B3B- K_{Ic} fracture toughness test – Geometric function formulae for semi-elliptical surface cracks in bi-axial bending. *Journal of the American Ceramic Society* 99, 249–256.

These examples show how established testing concepts can be transferred to other specimen geometries without sacrificing the basic principles of rigorous fracture toughness testing.

Other Methods: The Indentation Strength (IS) Method

Indentation cracks are perhaps the most simple way of generating pre-cracks on bend bars for fracture toughness measurements. However, if the residual stresses generated by the hardness indent are not removed, meaningful measurements are virtually impossible. This becomes obvious if the indentation-strength (IS) method is analyzed. For this method, a Vickers indentation pre-crack is introduced into a standard bend bar on the prospective tensile surface so that the diagonals are aligned parallel and perpendicular to the long axis of the bar. The bar is then fractured in bending and the fracture stress is determined. The fracture toughness is calculated from Young's modulus E , hardness H , the indentation load F and the fracture stress σ_f and a quantity η , which takes into account the residual stresses and the geometry factor of the crack.

$$K_{Ic} = \eta \left(\frac{E}{H} \right)^{1/8} \left(\sigma_f \cdot F^{1/3} \right)^{3/4} \quad (7)$$

The form of Eq. (7) has been derived by taking the combined loading of the crack by the residual stresses from the hardness indentation and the applied bending stress into account. This analysis shows that the indentation cracks grow to about 2.5 times their initial size during the bend test. Since neither the residual stresses nor the exact size of the crack at failure are known, the quantity η , which comprises the residual stress factor and the geometry factor Y can only be determined by experimental calibration Chantikul *et al.* (1981) to be $\eta = 0.59 \pm 0.12$. Strictly, conditions (iii) and (iv) are not satisfactory fulfilled for this test method. In a VAMAS round robin (Awaji *et al.*, 1990) the method was applied to a silicon nitride without R-curve behavior, among others. It turned out that the determined K_{Ic} was dependent on the indentation load, hence on the size of the pre-crack. This fact together with the large uncertainty of $\sim 20\%$ in η which directly transfers to an uncertainty in K_{Ic} , shows, that this method is not capable of delivering accurate values for the fracture toughness. Consequently it has not been standardized.

Indentation Fracture Resistance, The IF-Method

Instead of using an indentation crack as pre-crack in a strength test it seems to be even simpler to determine the fracture toughness directly from the lengths of the indentation crack. Unlike all other measurements reviewed so far in this contribution, this method uses arrested cracks – a fundamental difference, as pointed out by Quinn *et al.* (Quinn and Bradt, 2007).

Indentation cracks develop as a consequence of the wedging action which the irreversibly deformed zone around and under a hardness impression exerts. Apart from the two orthogonal half-penny cracks along the Vickers indentations diagonals, additional crack systems running parallel to the indented surface may be present (Cook and Pharr, 1990; Lube, 2001). The exact subsurface shape of the radiating cracks may depend on the indentation load (Pajares *et al.*, 1996) and the indented material. Relation between crack length and fracture toughness have been established using model descriptions of the loading and fracture toughness values

determined independently with different methods in order to find an empirical calibration constant. So far more than twenty different approaches have been published (a few can be found in the papers by Ponton *et al.* (Ponton and Rawlings, 1989a,b)). None of the relations works for all materials over a range of indentation forces and crack lengths.

Nevertheless the method seems to be so widespread and is believed to be indispensable for the investigation of small amounts of material that it was standardized for the measurement of a quantity called “indentation fracture resistance”. ISO 14627 (2012) is applicable to silicon nitrides for bearing balls, ISO 21618 (2019) is for all other monolithic and whisker or particle reinforced ceramics. In both standards it is explicitly noted – and shall be emphasized here – that the indentation fracture resistance “ $K_{I,IFR}$ ” is an estimate of a material’s resistance to cracking as introduced by an indenter and has correlations with wear resistance and rolling contact fatigue performance as well as machining processes, since these properties are governed by the resistance to crack extension in localized damage areas. By contrast, fracture toughness, K_{Isc} and K_{Ipb} are intrinsic properties of a material and are relevant to macroscopic and catastrophic fracture events with long cracks, rather than those phenomena caused by microscopic and successive damage accumulation associated with short cracks.” (ISO 21618, 2019).

It can be judged as beneficial that these two standards finally limit the range of applicable indentation loads to 20 kg and 10 kg (or 4.9 kg – only in ISO 21618), valid cracks and give defined procedures for the measurement of crack lengths and provide one single expression for the evaluation (Niihara *et al.*, 1982):

$$K_{I,IFR} = 0.000978 \left(\frac{E}{HV} \right)^{0.4} \left(\frac{F}{a^{1.5}} \right), \quad (8)$$

where HV is the Vickers hardness, F the indentation load in [N] and a the mean half surface crack length in [mm]. Along with the choice of the Eq. (8) goes the condition that only materials with a crack length to indent size ratio > 2.5 may be evaluated. Even if test circumstances are thus narrowed down and numbers measured on some ceramics fit proper SEVNB- or SCF-fracture toughness data, comparisons between different materials remain highly questionable. The method may appear to be quick and easy but it is still a subjective method.

Summary

Standardization of fracture toughness testing of ceramics has made a huge step forward in the last decade providing a wide choice of eligible methods. It has to be acknowledged that not all standardized methods work for all materials. Introduction and/or measurement of the pre-crack length on fracture surfaces is the major challenge.

The standardized methods work with pre-cracks that undergo different amounts of crack-growth before becoming critical. For materials exhibiting a rising crack resistance curve different methods may give different results. For a correct interpretation of a given fracture toughness value, the test method has to be known.

Since the properties of ceramic components are defined by the processing history it is favorable to machine specimens out of components. If this is not possible, standardized test methods may be adapted to be applicable to the components directly.

Arrested indentation cracks are useful to investigate the resistance to crack extension in localized damage areas but must not be used to measure the fracture toughness of ceramics.

R-Curve Behavior of Ceramics

Marc J Anglada, Polytechnic University of Catalonia, Barcelona, Spain

Basic Concepts on Fracture Mechanics

Ceramic materials fail by brittle fracture that originates at flaws, which can be generated during processing or in service. They are of different size and shape and they are distributed all through the material. Elastic fracture mechanics can be used to predict the strength when flaws are considered as very sharp cracks embedded in an elastic continuum. Cracks can propagate if the elastic energy released when they extend is larger than the energy necessary to create the new crack surfaces. The reader is referred to [Lawn \(1993\)](#) for background elastic fracture mechanics focused on ceramic materials.

The condition for fracture under a tensile stress acting perpendicular to the crack surface, that is, in mode I, can be also established in terms of the stress intensity factor, K_I , and the fracture toughness of the material, K_{Ic} . K_I describes the elastic stress field very near the crack tip and depends on the tensile stress, σ , the crack length, a , and the geometry of the specimen. Very often it can be written in a simple form,

$$K_I = \sigma Y \sqrt{\pi a} \quad (1)$$

In this expression Y is a geometrical factor which accounts for the loading mode, the geometry of the crack and of the specimen. Processing flaws in ceramic materials are generally very small in comparison to specimen dimensions, so that in this circumstance Y may be independent of the crack length. This is the case for a bulk small penny crack loaded in the direction perpendicular to the crack surface, where Y is equal to $2/\pi$ all along the crack front. K_{Ic} represents the critical value of K_I for which fracture occurs and it is in principle a material property. Therefore the fracture strength, σ_s , can be written as,

$$\sigma_s = \frac{K_{Ic}}{Y \sqrt{\pi a}} \quad (2)$$

This expression indicates that the fracture strength depends linearly on K_{Ic} and is inversely proportional to the square root of the crack length. It shows two possible strategies to increase the strength of ceramic materials, namely, increase the fracture toughness or decrease the defect size. From [Eq. \(2\)](#) it can be seen that the smallest strengths are associated with the largest flaws. Although specimens often contain many defects of different size, the strength will be determined by the larger crack size. On the other hand, if we know the strength of a specimen we can determine the minimum crack length or critical crack size for fracture. From [Eq. \(2\)](#) we obtain,

$$a_c = \frac{K_{Ic}^2}{\pi Y^2 \sigma_s^2} \quad (3)$$

In elastic fracture mechanics the strain release rate, G , is the energy available for unit of area of crack extension. Under plane strain in mode I, it is given by

$$G_I = \frac{K_I^2}{E} (1 - \nu^2) \quad (4)$$

where E is the Young modulus and ν the Poisson coefficient. Crack extension takes place when G reaches a critical value, G_{Ic} , which is the critical value for creating the unit surface of crack area. This is then related to the fracture toughness, K_{Ic} , by the above [Eq. \(4\)](#) at fracture,

$$G_{Ic} = \frac{K_{Ic}^2 (1 - \nu^2)}{E} \quad (5)$$

Units of G_I are energy per unit of area and are often expressed in kJm^{-2} while the units of K_I are stress per square root of length and it is often given in terms of $\text{MPa}\sqrt{\text{m}}$.

K_{Ic} and R-Curve Behavior

In the last section, K_{Ic} has been assumed to be a material parameter. However, in many structural ceramics the value of K_{Ic} depends on crack extension so that the fracture toughness cannot be considered to have a single value. In this situation, the material is characterized by a crack resistance curve ("R-curve") which represents the stress intensity factor that has to be applied by an external load for the onset and maintenance of crack extension. The R-curve behavior can be caused by several intrinsic effects as crack-face bridging, phase transformations, micro-cracking, etc. The effect of an increasing crack-resistance ("R-curve behavior") is commonly described by a function $K_R(\Delta a)$ in which K_R is the stress intensity factor necessary for crack propagation by an amount of Δa ([Fig. 1](#)). The R-curve is commonly obtained by inducing a long sharp crack and observing its stable extension as the stress intensity factor is increased until unstable fracture takes place. The condition for unstable fracture is now given by ([Anderson, 1995](#))

Fig. 1 (a) Schematic of an increasing crack growth resistance curve starting from the crack-tip toughness K_{I0} and exhibiting a saturation value $K_{R,max}$; (b) a crack in a ceramic material exhibiting crack surface interactions described by bridging stresses σ_{br} ; (c) distribution of bridging stresses versus distance to crack tip.

$$K = K_R \quad (6)$$

$$\frac{dK}{da} = \frac{dK_R}{da} \quad (7)$$

This means that for unstable fracture the functions K and K_R must have a common point where the tangents to both curves have the same value. The strength of a ceramic with R -curve behavior will be determined by the initial crack length as well as by the details of how much and how fast K_R increases with Δa .

Mechanisms Responsible for R -Curves

The critical stress intensity factor, K_{IC} (fracture toughness) of a ceramic that presents R -curve behavior is formally written as:

$$K_R = K_{IC} = K_{I0} + \Delta K_C \quad (8)$$

where K_{I0} is the intrinsic fracture toughness and ΔK_C the contribution from various crack-shielding mechanisms.

Grain Bridging

Coarse-grained materials present an R -curve effect which is caused by crack border interactions in the wake of an advancing crack (Swanson *et al.*, 1987). This fact has been proved experimentally in alumina with large grain size by re-notching experiments (Knehan and Steinbrech, 1982; Steinbrech *et al.*, 1983) and by in-situ observations under the electron microscope (Lathabai *et al.*, 1991). Then, the important mechanism for R -curve behavior is that of grains bridging the crack faces near the crack tip, that is, $\Delta K_C = |K_{br}|$ in Fig. 1.

In Fig. 2(a) friction bridging interaction by a friction force F is illustrated schematically. The crack face interactions localized at single grains can transfer loads which can be modeled in a more homogeneous way by the so-called bridging stresses σ_{br} that depend on the crack opening displacement δ . The bridging stresses shield the crack tip from the external loads as illustrated schematically in Fig. 2(b).

The bridging stresses depend on the crack opening displacement. When bridging is caused by friction effects, a simple relation between σ_{br} and δ is that proposed by Mai and Lawn (1987) and given in Eq. (9) in Table 1. Alternatively, another simple formulation of the bridging law is that of elastic bridging. In this event, bridges are assumed unbroken and can sustain a maximum stress, σ_0 (Eq. (10) of Table 1).

If it is assumed that the critical displacement for which the bridging stress vanishes, δ_c , follows the following function distribution density (Fett and Munz, 1993),

$$f(\delta_c) = \frac{1}{\delta_0} \left(\frac{\delta_c}{\delta_0} \right) \exp \left(-\frac{\delta_c}{\delta_0} \right) \quad (13)$$

Then, the macroscopically averaged bridging stress is given by:

$$\sigma_{br} = \int_0^\infty \sigma_{br} f(\delta_c) d\delta_c \quad (14)$$

The expressions obtained for the averaged bridging stresses for both bridging laws are given in Eqs. (11) and (12) of Table 1. Eqs. (10)–(13) are represented in Fig. 3.

Fig. 2 Crack surface interactions due to bridging forces (schematic): (a) local bridging events, (b) continuous bridging stress distribution. Table 1 Simple models for the bridging stress laws and the corresponding averaged bridging stresses

Model	Friction bridging	Elastic bridging
Bridging stress law	$\sigma_{br} = \begin{cases} \sigma_0 \left[1 - \left(\frac{\delta}{\delta_c} \right) \right] & \frac{\delta}{\delta_c} \leq 1 \\ 0 & \frac{\delta}{\delta_c} > 1 \end{cases} \quad (9)$	$\sigma_{br} = \begin{cases} \sigma_0 \left(\frac{\delta}{\delta_c} \right) & \frac{\delta}{\delta_c} \leq 1 \\ 0 & \frac{\delta}{\delta_c} > 1 \end{cases} \quad (10)$
Averaged bridging stress	$\sigma_{br} = \sigma_0 \exp \left(-\frac{\delta}{\delta_0} \right) \quad (11)$	$\sigma_{br} = \sigma_0 \left(\frac{\delta}{\delta_0} \right) \exp \left(-\frac{\delta}{\delta_0} \right) \quad (12)$

Fig. 3 Local (a) and global (b) bridging relations for friction and elastic bridging.

Phase Transformation Toughening in Zirconia Ceramics

In phase transformation zirconia ceramics, the main contribution to toughening is related to the stress activated t-m phase transformation in the crack tip process zone, where the stress reaches high values. The transformation is accompanied by an increase in volume which in turn creates a compressive strain field which opposes crack extension. If the transformation induces a strain ϵ^T in the unconstrained material, forces must be then applied on the contour of the transformed material in order to restore its original shape (Fig. 4). If the transformation is only dilatational, these forces are normal pressure inducing a tip shielding stress intensity factor. The maximum contribution to the toughness, ΔK_{CT} , resulting from the stress activated transformation is given by,

$$\Delta K_{CT} = \frac{\eta E^* \epsilon^T V_f w^{1/2}}{1 - \nu} \quad (15)$$

Fig. 4 Stresses in a dilatant transformation zone. The zone must be reduced in size from its unconstrained size to fit in the untransformed material. Once the zone extends behind the crack tip, stresses in the zone arise that are acting in a direction to close the crack. Reprinted from Green, D.J., Hannink, R.H.J., Swain, M.V., 1989. *Toughening of Ceramics*. Boca Raton: CRC Press with permission of CRC Press. All rights reserved.

Fig. 5 Zone shape parameter η for Ce-TZP in terms of transformation aspect ratio d/w (see the insert) (Marshall, D.B., 1990. Crack shielding in ceria-partially-stabilized zirconia. *J. Am. Ceram. Soc.* 73, 3119–3121). The values of generally assumed transformation morphologies are indicated. Reprinted from Hannink, R.H.J., Swain, M.V., 1994. Progress in transformation toughening of ceramics. *Annu. Rev. Mater. Sci.* 24, 359–408 with permission of CRC. All rights reserved.

where η is a factor depending on the zone shape at the crack tip and on the nature of the stress field in that zone. Its value is equal to 0.22 for a pure dilatational transformation, V_f is the volume fraction transformed, w is the width of the transformation zone from the crack surface (i.e., the half-height of the zone) and ν is the Poisson coefficient (McMeeking and Evans, 1982). The matrix modulus E^* plays an important role in determining the effectiveness of the dilatational strain. For example, a stiffer matrix, such as Al_2O_3 ($E^* = 380$ GPa, $\nu = 0.2$), constrains the zirconia transformation more than does ZrO_2 ($E^* = 210$ GPa, $\nu = 0.3$) decreasing the extent of the transformation zone w , because of the high matrix E^* value that opposes the transformation. For a review of transformation toughening of zirconia ceramics see Hannink *et al.* (2000).

The transformation zone around the crack tip in Ce-TZP does not follow the nearly circular phase transformation zones which are found in MgO-doped zirconia, but typically extends some 10–20 times the zone width ahead of the cracks (Yu *et al.*, 1992). Although Eq. (15) still holds for the increase in toughness, the parameter η of this equation for Ce-TZP depends on the aspect ratio of the transformation zone (Fig. 5). For a 9 mol% Ce-TZP the transformation zones are shown in Fig. 6 for two sintering temperatures, 1400 and 1600°C, with resulting average tetragonal grain sizes of 0.9 and 2.5 μm , respectively (Rauchs *et al.*, 2002). At the lower sintering temperature the transformation zone is extremely narrow while at the higher temperature is wider and irregular in shape.

Fig. 6 Transformation shapes observed in 9 mol% Ce-TZP for two sintering temperatures: (a) top 1600°C, (b) bottom 1400°C with resulting average tetragonal grain sizes of 2.5 and 0.9 μm , respectively. Fig. 7 Schematic illustration of the stress-induced domain switching in PZT.

Domain Switching in Piezoelectric Ceramics

Many materials have been studied as practical piezoelectric ceramics over the years. Most of them are still based on lead zirconate titanate ($\text{Pb}(\text{Zr,Ti})\text{O}_3$), which is a solid solution of PbZrO_3 and PbTiO_3 and it is referred as PZT. Most ferroelectric ceramics undergo a displacive structural phase transition from a high temperature prototype phase (often centrosymmetric) into one or more ferroelectric phases of lower symmetry. After cooling below the Curie temperature, the polarization of a ferroelectric polycrystal is zero because of the spontaneous polarization into domains, separated by domain boundaries, and with different polarization directions so that no net polarization results. The net polarization occurs when an electrical field is applied and the domains switch in the direction of the field, that is, the ceramic is poled. Switching of domains also takes place by the action of stress. If the stress applied is tensile, the polarization of the domains switch to the direction of the stress inducing a small increase in the length of the sample in this direction, while if the stress applied is compressive the domains switch in a direction with the polarization perpendicular to the stress resulting in a contraction of the sample. In a small zone very close to the crack tip (Fig. 7), the stress is high enough for switching the direction of the domains leading to non-linear deformation of the material inside this zone and a corresponding residual stress, similarly to the

stress activated phase transformation of zirconia, which increases when the crack extends (Chen and Lynch, 1998; Schneider and Heyer, 1999; dos Santos e Lucato *et al.*, 2000; Fett *et al.*, 2000a).

The effect of the applied stress on a poled ceramic will depend on the polling direction in front the crack tip. Thus, if the polling direction is the same as the applied tensile stress the effect will be small since few domains will switch to the stress direction as most of them are already oriented in this direction. On the contrary, if the polling direction is perpendicular to the applied stress, for example in the direction of the crack propagation direction, the domains will tend to switch in order to align with the stress field. This induces a strong anisotropy in the fracture toughness of poled piezoelectric ceramics as shown from experiments with Vickers or Knoop indentations cracks (Fett and Munz, 2000). This is mainly attributed to the different switching ability of domains lying in the crack tip stress field.

The highest plateau of *R*-curves of lead zirconate titanate in compact tension (CT) specimens is obtained when the polling direction is in the thickness direction (dos Santos e Lucato *et al.*, 2000). The lowest value is obtained when polling is in the direction of the applied stress, while for the unpoled material the toughness is between both values. By using specimens of different thickness and poled in the thickness direction, it has been concluded that the low coercive stress is responsible for the development of a large switching zone, which is of high relevance for the computation of the actual stress intensity factor at the crack tip and for the *R*-curve calculation (Fett *et al.*, 2005b; Njiwa *et al.*, 2006).

Microcrack Zone and Crack Deflection and Branching

Another toughening mechanism that involves crack-tip shielding is “microcrack toughening.” Microcracks can form in a zone close to the tip of large cracks in the grain boundaries of ceramics that contain localized residual stresses in a similar way as a stress-induced phase transformation zone forms (Buresch, 1978; Pabst *et al.*, 1978). Microcracks reduce the elastic modulus near the crack tip giving rise to shielding. Alternatively, in terms of energy considerations, by increasing the effective fracture surface, the effective critical energy release rate is also increased. As the crack extends, an increase of the damage zone will increase the fracture resistance. The formation of microcracks in the residual stress field could also give rise to a volume increase if the microcracks open. This effect can be formally treated by the transformation toughening equation of increase in fracture toughness. An increase in fracture toughness is expected since, as the crack extends, the microcracks enter the crack wake where dilation toughening will occur. Nevertheless, another effect specific to the formation of microcracks is that they degrade the material in front of the crack tip, so that the fracture toughness of this zone is lower than that of the non-microcracked ceramics. A mechanics model of microcrack toughening predicts the magnitude of microcrack toughening as well as the existence of *R*-curve effects (Evans and Faber, 2006). The toughening was attributed to both the elastic modulus diminution in the microcrack process zone and the dilatation induced by microcracking. The dilatational effect is potentially more substantial, as well as being the primary source of the *R*-curve. The analysis of the theoretical model also demonstrated that microcrack toughening is less potent than transformation toughening.

The mechanisms described so far act in the crack wake (that is, after crack extension commences) to resist crack propagation through crack-tip shielding mechanisms and they are referred to as extrinsic in contrast with those acting in front of the crack tip which as referred to as intrinsic. A potential increase in the crack growth resistance takes place when a crack bifurcates in two or more cracks since then the energy release rate is reduced because of the increase in crack surface. In ceramic laminates with strong interfaces a high increase in crack growth resistance is observed under compressive residual stresses perpendicular to the crack. In ceramic laminates with weak interfaces, a crack approaching the weak interface may be kinked along the interface which may result in a reduction of the crack driving force stopping the crack along the interface, so that applied stress intensity factor has to be increased to propagate the crack. The *R*-curves of ceramic laminates are described in Section “*R*-Curve in Ceramic Laminates”.

In general, several toughening mechanisms giving rise to *R*-curve behavior are simultaneously present. For example, the *in vitro* toughness of mineralized tissues illustrates the critical role of microstructure in the mechanisms of fracture at the macro-micro and nano-scales (Launey *et al.*, 2010). There is a mutual competition between extrinsic (crack-tip shielding) toughening mechanisms, which predominate at length scales at more than 1 μm , and intrinsic (plastic deformation) toughening mechanisms, which are active at length scales at primarily less than 1 μm (see Fig. 3 in Launey *et al.*, 2010). Distinct toughening mechanisms occur at each level of hierarchy. In these materials, the observed extrinsic mechanisms liable to contribute to *R*-curve behavior are microcracking, bridging by collagen fibers and uncracked ligaments and crack deflection due to crack–osteon interactions (Nalla *et al.*, 2003). However, in spite of the existence of different mechanisms, there is strong experimental evidence that crack bridging rather than constrained microcracking is dominant. The prime source of such bridging in human bone appears to be from the formation of uncracked ligaments in the crack wake, which are created either by the non-uniform advance of the crack front and/or by the imperfect linking of microcracks ahead of the crack tip with the main crack (Nalla *et al.*, 2005). High anisotropy in crack resistance curves in relation to the osteon direction is also present as can be appreciated in Zimmermann *et al.* (2015). It is also interesting to note that aging changes the *R*-curves of human bone resulting a decrease in the crack initiation toughness as well as in the crack-growth toughness, the latter being associated to higher osteon density and lack of uncracked ligaments bridges in aged tissue (Zimmermann *et al.*, 2011).

Determination of K_{Ic} and K_{R} Curves

Long Cracks

The principal procedure for the determination of K_{Ic} and K_R curves consists in the generation of a sharp long crack in a test specimen of simple geometry for which the stress intensity factor is very well known. From a test in which the load is recorded and

Fig. 8 Geometry for a four point bending specimen with and edge notch.

the crack length is directly observed with a travelling microscope, the applied stress intensity factor can be calculated and plotted in terms of the increase in crack length.

The test specimens most used are three and four point bending specimens with a thickness $B = 3$ mm and height $W = 4$. **Fig. 8** shows a four point bending specimens with the inner roller span, S_2 , of generally 20 mm, and the outer one, S_1 , of 40 mm. Three point bending specimens, that is, $S_2 = 0$ in **Fig. 8** and $S_1/W > 2.5$ are also used specially when there is limited material availability for testing. For both configurations the stress intensity factor can be formally written as:

$$K_I = \sigma \sqrt{a} Y \left(\frac{a}{W} \right) = \frac{F}{B \sqrt{W}} Y^* (a/W) \quad (16)$$

with

$$Y^* = \sqrt{\frac{a}{W}} Y \quad (17)$$

Expressions for Y^* for three and four point bending specimens can be found in [Rauchs et al. \(2002\)](#) and [Munz and Fett \(1999\)](#), respectively.

For the calculation of K_{IC} , the failure load and the crack length are introduced in [Eq. \(16\)](#). If the material exhibits crack resistance curve, the crack grows stably and the load and corresponding crack length at final fracture have to be determined. The two most used procedures are to measure in situ the crack growth at the specimen surface with an optical or electron microscope, or by an indirect method based on measuring the change in compliance, C , as the crack extends. In this occasion, the load point displacement, u , needs to be known accurately. From the slopes of partial unloading curves during crack growth the compliance ($C = u/F$) can be determined and from this the crack length ([Jelitto et al., 2007](#)).

In **Fig. 9** a very rigid bending test device is shown which was used for determining the R -curve in three-point bending with a roller span of 40 mm. The load and the load point displacement were simultaneously recorded and the crack length measured with a microscope. The crack length obtained via compliance was compared with the physical crack length visible on the surface. **Fig. 9** also displays the partial unloadings carried out during the test to measure the evolution of the compliance as the crack grows. The crack length can be obtained by previous calibration of compliance against that measured with test specimens of identical geometry with sharp saw cuts of specific lengths. The compliance can be also calculated by using an expression of C in terms of Y^* which can be obtained from the equation relating the energy release rate G_I with the compliance. For a plate of thickness B with a through-the thickness crack ([Anderson, 1995](#))

$$G_I = \frac{F^2}{2BW} \frac{dC}{d(a/W)} \quad (18)$$

By using this equation, the expression that results for the compliance in terms of $Y^*(a/W)$ is

$$C = C_0 + \frac{2}{BE'} \int_0^a Y^{*2}(\alpha') d\alpha' \quad (19)$$

C_0 is the compliance of the specimen in the absence of a crack or notch. From $\Delta C = C - C_0$, the normalized crack length a/W can be determined. Very often the compliance measured with actual cracks is lower than with saw cuts of the same length. The reason is the presence of bridging between the crack surfaces, which contributes to decrease the experimental compliance and can underestimate the length of the actual crack. In materials with strong R -curve behavior this effect can be important.

The Starting Notch for the Determination of Fracture Resistance

Another important point for measuring K_{IC} and K_R -curves is the need to use specimens with a very narrow notch. Usually narrow saw cuts induce notch tips radii too large for testing very fine grained ceramics. In this situation, a narrow V-notch is machined at the notch tip by using a razor blade with diamond paste ([Nishida et al., 1996](#); [Kübler, 1997](#)). In this way, the notch tip can be considerably sharpened inducing crack tip radii which sometimes can be smaller than 10 μm . However, the production of very sharp V-notches in a controlled manner is not straight forward.

Fig. 9 At the top the rigid load rig used for the *R*-curve experiments. Bottom load-displacement diagram of 9 mol% Ce-TZP: (a) sintered at 1600°C with 2.5 μm grain size and (b) sintered at 1400°C with 0.9 μm grain size. Reprinted from Rauchs, G., Fett, T., Munz, D., 2002. *R*-curve behavior of 9Ce-TZP zirconia ceramics. *Eng. Fract. Mech.* 69, 389–401 with permission of Elsevier. All rights reserved.

Fett (1999) analyzed the stress intensity factor of a notch (with a tip radius R) and length a_0 with either an edge trough the thickness straight microcrack or a semicircular crack of length l in front of the notch tip. Microcracks are usually produced by the machining process and have dimensions typically in the range of 1–3 times the grain size (d). In coarse ceramics it is feasible that $l \sim 3d > R$ (Damani *et al.*, 1996), but as finer grain size ceramics are tested, this condition is more difficult to fulfill. For example, for 3Y-TZP, which is widely used for biomedical applications with an average grain size $d \sim 0.33 \mu\text{m}$ ($l \sim 1 \mu\text{m}$), R should be less than 1 μm , and this is not possible to achieve in practice by the method of the razor blade. Therefore, it may be not justified to take $a_0 + l$ for the crack length in the calculation of K_{Ic} or the K_R -curves. It is then expected that if K_{Ic} is measured from notches the value is overestimated since the stress field in front of a notch is more moderate than in front of a crack. This was shown in submicron grain size 3Y-TZP by testing a large number of samples with notch radii in the range 18 and 167 μm . The experimental values of K_{Ic} were strongly affected and ranged from 5.9 to 13.6 $\text{MPa m}^{1/2}$, respectively (Fischer *et al.*, 2008). For the correct determination of this property in submicron grain size ceramics, sharper starting V-notches are required.

A modified compliance method has been introduced for small cracks of length l emanating from the root of finite notches machined by the razor blade procedure, and it has been shown that the notch root radius, R , strongly affects the formally computed crack resistance curve (Fett *et al.*, 2008). Tests were performed on a silicon nitride with 5 wt% Y_2O_3 and 2 wt% MgO and with the modified compliance method it was shown how the initial true *R*-curve can be obtained from the data, finding a very steep *R*-curve with the saturation reached after only about 10 μm crack extension. An upper limit was found for the crack tip toughness of 3.6 $\text{MPa m}^{1/2}$, whereas the conventional procedure without considering the effect of the notch would yield an unrealistically high value of about 6.3 $\text{MPa m}^{1/2}$. The modified compliance method and the conventional procedure yield comparable results for $l > 2R$.

One method to machine very shallow single edge V notches on the surface of rectangular bending bars is by ultra-short pulsed laser ablation. In recent studies for the determination of K_{Ic} in 3Y-TZP (Turón-Vinas and Anglada, 2014) and Si_3N_4 (Turón-Vinas and Anglada, 2015) this technique was used. Fig. 10 shows the micro-notch with the microcracked zone in front of the micro-notch machined by ultra-short pulsed laser ablation. From these studies it was concluded that: (1) the technique is very suitable for measuring K_{Ic} in nanograin size specimens in which it is impossible to produce sharp notches with enough small tip

Fig. 10 (a) Micro-notch with tip radius below the micron induced by ultra-short pulsed laser ablation; (b) detail of the microcracked zone in front of the micronotch. Reprinted from Turon-Vinas, M., Anglada, M., 2014. Fracture toughness of zirconia from a shallow notch produced by ultra-short pulsed laser ablation. *J. Eur. Ceram. Soc.* 34, 3865–3870 with permission of Elsevier. All rights reserved.

radius by conventional methods; (2) although the notch tip radius induced by ultra-short pulsed laser ablation is of dimensions in the sub-micrometer range, the starting crack is the result of coalescence of very sharp microcracks induced by ultra-short pulsed laser ablation in front of the micro-notch tip; (3) the value obtained for K_{Ic} is inside the range of values quoted for 3Y-TZP and Si_3N_4 but rather in the lower values of the range.

K_R -Curves From Strength Measurements From Indentation Cracks

Measurements of the instability of long, well defined cracks are, in principle, of little relevance to the strength and reliability of ceramics. R -curves from cracks which are able to imitate service flaws are required for a sound design strategy with ceramics. In this sense, many R -curves have been evaluated from Vickers and Knoop indentation cracks (Lawn, 1993). During indentation, up to a maximum load, P , and during unloading, a crack system develops, where the details depend on the materials and on the maximum load. Three crack types are observed: radial cracks extending from the edges of the indentation at the surface, median cracks extending below the tip of the indentation, and lateral cracks parallel to the surface. In some occasions the radial and median cracks combine after unloading to semi-circular or semi-elliptical surface cracks. Compressive stresses are induced below the contact area after unloading while residual tensile stresses are produced away from the contact area. The model generally used to describe the stress intensity factor of the residual tensile stresses is that of an opening load at the crack center, whose magnitude is proportional to the indentation load. The residual stress intensity factor for a semi-circular crack is (Lawn, 1993)

$$K_r = \chi P c^{-3/2} \quad (20)$$

where c is the radius of the crack and χ is a constant which depends on the material. K_r decreases during crack extension until $K_r = K_R$. If an external stress is applied, the crack can grow in a stable manner to a new crack length for which the superposition of the applied and residual stress intensity factor equals the K_R -curve,

$$K_t = K_{appl} + K_r = Y \sigma \sqrt{c} + \chi P c^{-3/2} = K_R(c) \quad (21)$$

The fracture stress σ_c can be calculated by imposing the two conditions given in Eqs. (6) and (7). If $K_R(c)$, Y and χ were independent of c , a plot of $\log \sigma_c$ versus $\log P$ then leads to a straight line with slope of $-1/3$ (Chantikul et al., 1981). In materials with a rising crack growth resistance, the $\log \sigma_c - \log P$ curve has a slope that decreases with decreasing P (Lawn, 1993). For small indentation loads, failure does not occur anymore from indentation cracks since it originates from natural flaws. One important

Fig. 11 First estimation of the R -curve, computed for fixed $a/c = 0.95$; (a) initial crack depths, (b) applied stress intensity factors for several initial crack depths (thin curves), (c) first estimation of the R -curve (thick curve). Reprinted from Fett, T., Munz, D., 2013. Fracture mechanics. In: Handbook of Advanced Ceramics. Elsevier. pp. 681–715 with permission of Elsevier. All rights reserved.

limitation of this method is that Y and χ need to be known and they must be constant during stable crack growth. The parameter χ depends on elastic modulus, E , and hardness, H (Lawn *et al.*, 1980):

$$\chi = \xi \left(\frac{E}{H} \right)^{\frac{1}{2}} \quad (22)$$

The value of the constant ξ often used is 0.016 which is the value proposed by Anstis *et al.* (1981). When an external stress is applied there is a reduction in K_r as shown for Vickers (Fett, 1995a), and Knoop (Fett and Rizzi, 2003) indentation cracks. Uncertainties in the residual stresses and the value of χ can be avoided by polishing away the elastic-plastic zone or annealing before testing in order to remove residual stresses. Nevertheless, care is needed to take into consideration the small change in the crack shape after polishing and any change induced during the annealing process on the microstructure at the crack tip or in the bridging stress between the crack surfaces.

One of the simpler methods for measuring the R -curve from indentation cracks consists on measuring the strength of tensile or bending specimens with surface Knoop indentation cracks induced with a range of indentation loads and with residual stresses removed by annealing. These cracks have an approximate semi-elliptical shape and the applied stress intensity factor changes along the crack front having different values at the deepest point (K_{IA}) and at the surface (K_{IB}), see Fig. 11(a). Then the crack starts to extend if $K_{IA}, K_{IB} > K_{I0}$, where K_{I0} is the intrinsic fracture toughness. Final fracture takes place after some stable crack extension at the deepest point, $\Delta a = a - a_0$, and at the surface, $\Delta c = c - c_0$. Then the conditions for final fracture (Eqs. (6) and (7)) applied to the surface and to the deepest point of the semi-circular crack are:

$$K_{IA} = K_{IR}(\Delta a), K_{IB} = K_{IR}(\Delta c) \quad (23)$$

$$\max \left(\frac{\partial(K_{IA} - K_{IR}(\Delta a))}{\partial a}, \frac{\partial(K_{IB} - K_{IR}(\Delta c))}{\partial a} \right) \geq 0 \quad (24)$$

Fett and Munz (2000) evaluated the R -curve under several simplifying assumptions: (1) the aspect ratio is fixed ($a/c = a_0/c_0 = \text{const.} = 0.95$) during crack extension; (2) the R -curve is independent of a_0 ; (3) the geometrical functions of the stress intensity factor at points A and B are identical and equal to their average value. The applied stress intensity factors computed with the measured strengths, σ_c , are given by Eq. (1). They are plotted for different values of a_0 in Fig. 11(c), with σ_c taken from Fig. 11(b). The resulting curves of K_{app} versus Δa are shown in Fig. 11(c) for each initial crack length. The R -curve resulting from the envelope condition is displayed as a thick line. It can be noticed that K_{IR} increases strongly with crack extension Δa . By dropping the assumption of a constant aspect ratio similar R -curve was obtained.

Stress Intensity Factor From Bridging Interactions

If the R -curve is produced by bridging stresses in the crack wake, these can be computed with the use of fracture mechanics weight functions and the experimental measurements of the R -curve. The specimen is loaded by an external load, which would lead to a stress distribution $\sigma_{appl}(x)$ at the location of the crack in the uncracked component (Fig. 12). The total stress is the sum of the applied stress, σ_{appl} , and the bridging stress, σ_{br} :

Fig. 12 Specimen with a crack with a bridging stress distribution.

$$\sigma(x) = \sigma_{appl}(x) + \sigma_{br}(x) \quad (25)$$

The bridging stress intensity factor, K_{br} , can be expressed in terms of the weight function, $h(x, a)$, which is a function of the crack length a and the coordinate x . Weight functions are used in fracture mechanics to calculate stress intensity factors because they are independent of the load applied and only depend on the geometry of the component. K_{br} in terms of $h(x, a)$ is given by

$$K_{br} = \int_0^a h(x, a) \sigma_{br}(x) dx \quad (26)$$

and for the applied stress intensity factor K_{Iappl} :

$$K_{Iappl} = \int_0^a h(x, a) \sigma_{appl}(x) dx \quad (27)$$

The weight functions are known for many types of test specimens and can be found in [Wu and Carlsson \(1991\)](#). The total stress intensity factor at the crack tip is then given as

$$K_{Itip} = K_{Iappl} + K_{Ibr} \quad (28)$$

In order to obtain σ_{br} and K_{Ibr} an expression for the total displacements of the crack surface, δ , can be derived by the existing relation between crack surface displacements, weight function and stress intensity factor for a given stress distribution $\sigma(x)$ ([Anderson, 1995](#)):

$$h = \frac{E'}{K_I} \frac{\partial \delta(x, a)}{\partial a} \quad (29)$$

E' is the elastic modulus in plain strain. Integration of this formula and applying [Eq. \(28\)](#) yields the crack surface displacements δ caused by the total stress σ of [Eq. \(25\)](#):

$$\delta(x) = \delta_{br}(x) + \delta_{app}(x) = \frac{1}{E'} \int_x^a h(x, a') \left[\int_0^{a'} h(a', x') (\sigma_{appl}(x') + \sigma_{br}(x')) dx' \right] da' \quad (30)$$

with

$$\delta_{br}(x) = \frac{1}{E'} \int_x^a h(x, a') \left[\int_0^{a'} h(a', x') \sigma_{br}(x') dx' \right] da' \quad (31)$$

$$\delta_{app}(x) = \frac{1}{E'} \int_x^a h(x, a') \left[\int_0^{a'} h(a', x') \sigma_{appl}(x') dx' \right] da' \quad (32)$$

where x is the coordinate of the point where the displacement is computed and x' is the location where the stress σ acts.

Determination of the Bridging Parameters From the K_R -Curves

A procedure that allows the bridging stresses to be determined from experimental R -curve was developed and applied to the R -curve of qcoarse-grained alumina ([Fett, 1995b](#); [Fett et al., 1995](#)). Later on, it was applied by [Fünfschilling et al. \(2009\)](#) to the

R-curves of silicon nitrides obtained by a high-resolution compliance method (Fett *et al.*, 2008). The procedure of the determination of the bridging stresses will be shown for these two silicon nitrides (Y₂O₃, MgO)-SN and (Al₂O₃, MgO)-SN which were consolidated in a two step sintering process.

The simplest approach to solve Eqs. (26)–(30) is to express the bridging law by a series expansion with respect to δ with unknown coefficients A_n ,

$$\sigma_{br}(\delta) = \sum_{n=0}^N A_n \delta^n \quad (33)$$

For a given arbitrary crack length, a , δ is first approximated by δ_{appl} . By using this value of δ , $\sigma_{br}(\delta)$ can be obtained from Eq. (33) with an arbitrarily chosen set of coefficients A_n . This first approximation for the bridging stress is then inserted in the integrand of Eq. (30), so that an improved solution for the total displacement is obtained. The procedure is then repeated by entering the δ -values in Eq. (33) for obtaining an improved bridging stress. The procedure is iterated until a certain state of convergence is reached. This part of the calculation forms the inner loop of a computer program. In the outer loop, the actual crack length is varied by $\Delta a = a - a_0$, and K_{br} is computed using Eq. (30). Then, from Eq. (28)

$$K_R = K_{lappl} = K_{ltip} - K_{lbr} \quad K_{lbr} < 0 \quad (34)$$

If this is repeated for a number of N crack length values, we obtain N computed K_R -values. A second iterative procedure is then applied in which the N coefficients are changed systematically until computed and measured K_R are identical (Fett *et al.*, 1995; Fünfschilling *et al.*, 2009). The results for the two silicon nitrides are plotted in Fig. 13. This method is computationally expensive, so that recently approximations have been developed that significantly reduce the computational time (Fünfschilling *et al.*, 2010). The crack tip displacement corresponding to the Irwin parabola is given by (Anderson, 1995)

$$\delta_{br,tip} = \sqrt{\frac{8 K_{br}}{\pi E}} \sqrt{a - x} \quad (35)$$

Eq. (35) is plotted in Fig. 13(d) for the same bridging stress intensity factor (dashed curve) as the exact solution given by Eq. (31) for $\Delta a = 100 \mu\text{m}$.

Effect of Specimen Geometry, Crack Size, and Type of Loading on the *R*-Curve

The *R*-curve is not a material property (Fett and Munz, 1990). It depends on the geometry of the component, the initial crack size, and the type of loading. This has been shown experimentally and by calculations using different type of specimens. Thus, the results of calculations of the bridging stress intensity factor using the same bridging relation are shown in Fig. 14 for different type of specimens (Fett *et al.*, 2000b).

The initial crack size also influences the *R*-curve as shown experimentally by Steinbrech *et al.*, 1990 in SENB specimens of Alumina (Fig. 15). Long initial cracks were produced by saw cutting, so that no wake or initial process zone was initially present.

Long and Small Cracks

R-curves for naturally small cracks are often different from those for macroscopic cracks, showing the trend of lower *R*-curves for small natural cracks. This is illustrated in Fig. 16 for Mg-doped zirconia and Alumina. The *R*-curves of small semielliptical surface flaws of silicon nitrides and carbides can be also different from those measured with long through-thickness cracks, particularly with regard to the initiation toughness and initial slope. For example, Li and Yamanis (1989) found that the *R*-curve in a Si₃N₄ ceramic using indentation-strength measurements rose more steeply than that measured from a double-cantilever beam specimen.

In silicon carbide, the *R*-curve behavior for small surface cracks and long through thickness cracks were studied in two SiC ceramics with sharply contrasting fracture properties (Gilbert *et al.*, 2005). The first was a commercial SiC (Hexoloy SA) that failed by transgranular cleavage without any evidence of crack shielding; the second one (referenced as ABC-SiC) had a microstructure formed by a network of plate-shaped grains with an amorphous grain-boundary film promoting debonding and crack deflection and resulting in toughening from a bridging generated *R*-curve. Hexoloy SA failed catastrophically at $K_{Ic} < 3 \text{ MPa m}^{1/2}$, while ABC-SiC exhibited much-improved flaw tolerance with significant rising *R*-curve behavior and a steady-state fracture toughness of $\sim 9 \text{ MPa m}^{1/2}$ after crack extension of $\sim 600 \mu\text{m}$. In ABC-SiC, however, the behavior of long and small cracks were very different for crack sizes extensions of less than $\sim 120 \mu\text{m}$, with the small-cracks showing much less crack-growth resistance; this effect was not observed in Hexoloy SA (Fig. 17).

According to Gilbert *et al.* (2005) this discrepancy in long- and small-crack *R*-curves at initial crack extensions was not caused by variation in the shape of the crack wake, but rather by the physically small nature of the crack, relative to grain size and local residual stress fluctuations. Fett *et al.* (1996) demonstrated that differences in the shape of the crack-opening profile for small surface cracks versus long through thickness cracks alters the initial slope of the *R*-curve, because of changes in the distribution of bridging tractions. However, according to Gilbert *et al.* (2005) these bridging tractions cannot explain the large decrease in initiation toughness and crack-growth resistance for small cracks compared to long cracks.

Determination of Bridging Stresses

As can be seen from previous sections, crack bridging is an important mechanism for the crack propagation resistance. The *R*-curve depends on different factors such as specimen geometry, initial crack length, etc. Nevertheless, the bridging stress distribution as a function of crack opening displacement is widely believed to represent a true material property uninfluenced by sample geometry,

loading conditions, and other extrinsic factors (Greene *et al.*, 2012). A short description of existing methods for accurate measurement of the bridging stress distribution are presented below.

The Multi-Cutting Compliance Technique

The multi-cutting compliance technique is destructive and involves measuring the compliance after incremental saw cuts are made into the wake of a bridged crack (Hu *et al.*, 1991; Hu and Mai, 1992). It uses a diamond saw blade to incrementally cut away the crack wake while measuring the sample compliance via back-face strain gauges. Crack-opening profile measurements are also made and used along with the results of multi-cutting compliance experiments to obtain an estimate of the full bridging stress distribution. When the portion of crack wake eliminated is traction free, there is no change in compliance after cutting; conversely, if active bridges are removed from the crack wake by the saw blade, a corresponding increase in the sample compliance is expected. Thus, the extent of the grain-bridging zone behind the crack tip, L , may be determined by observing the notch length where the compliance begins to increase during the multi-cutting experiment. When the bridging-zone length is appreciably smaller than the sample size, the normalized grain-bridging stress distribution $\sigma_{br}(x)/\sigma_{max}$ can be obtained from the measured compliance during the multi-cutting experiment. σ_{max} is then determined by calculation of Eq. (35) by a least-squares fit to the experimental data of the measured bridged crack-opening profile. When L is of the order of the crack length the solution of Eq. (31) is facilitated by using an approximation (Wittmann and Hu, 1991; Kruzic *et al.*, 2004).

The Post-Fracture Tensile (PFT) Test

Hay and White (1993, 1995) developed the post-fracture tensile test (PFT) from cracked DCB specimens with the objective of determining directly the closure stress in terms of crack opening displacement. Small post fracture tensile specimens are machined by sectioning larger cracked ceramic specimens. These post fracture specimens are cut in such a way that they span the crack wake of the DCB specimen. Each one contains a portion of the original bridged through-thickness crack which can then be tensile tested. The separation between crack faces in the tensile test of the sliced specimens can be measured by using a laser interferometric displacement gauge. The wake stiffness and peak load capacity of the sliced specimens are measured, finding higher values for those closer to the crack tip. In alumina with coarse grain size the evaluation of the initial part of the R -curve combined with the results of post-fracture tensile tests allow the total bridging stress relation to be determined. The post fracture tensile tests provided the bridging stresses for larger displacements (Fett *et al.*, 2000c). One important limitation of this technique is the spatial resolution which is limited by the size of the width of the post fracture tensile specimens.

Soc. 83, 421–423 with permission of the American Ceramic Society. All rights reserved.

Calculation of Bridging Stresses From Experimental Crack Profiles

A method to determine the bridging stress relation is based on the measurements of crack opening displacement (COD) during stable crack propagation (Fett *et al.*, 1994; Fett *et al.*, 2005a). The procedure is, in principle, based in Eq. (34) where the left-hand side is known as the result of the COD measurements. The bridging stress distribution $\sigma_{br}(x)$ is the magnitude to be found. The integral equation can be solved numerically. In Fig. 18(a) the experimental COD for coarse alumina is shown in terms of the distance to the crack tip as well as the COD that would exist for a given applied stress intensity factor ($K_{appl} = 3.75 \text{ MPa m}^{1/2}$) without bridging effects. The evaluation of these data via Eq. (34) yields the bridging stress law plotted in Fig. 18(b) (Fett *et al.*, 2000d).

Bridging Stresses From Raman and Fluorescent Spectroscopy

Fluorescent and Raman spectroscopy based methods can be used to measure bridging stresses in various ceramic base materials. Fluorescent spectroscopy has been used mainly in alumina because of the usual presence of Chromium as a substitution impurity. The optical fluorescence lines of Cr^{+3} are shifted by the stress from their stress-free position. The bridging stresses in the wake of the crack path were measured by fluorescence spectroscopy in large-grained alumina polycrystals (Pezzotti *et al.*, 1998). Frictional bridging stresses were $\approx 50 \text{ MPa}$, while unbroken ligaments between the crack faces were found to support tensile stresses up to $\approx 100 \text{ MPa}$. Average bridging stresses, either theoretically calculated from *R*-curve data or experimentally measured by fluorescence spectroscopy on frictional/bridging sites, were similar.

The peaks of the Raman spectrum are also sensitive to stress so that Raman spectroscopy has also been used for determining bridging stress profiles. In toughened Si_3N_4 with a remarkably rising *R*-curve behavior, using this technique tractions of the GPa order were determined during crack mouth opening experiments with unbroken acicular grains placed in the very neighborhood behind the advancing crack tip (within a crack length $0 < \Delta a < 100 \mu\text{m}$). Closure stresses up to values of several hundred MPa were measured in a zone up to several hundred microns behind the crack tip by friction of broken interfaces. Their magnitude averaged upon the frictional bridging zone, $100 < \Delta a < 800 \mu\text{m}$, was only 120 MPa, thus providing only a minor contribution to toughening. The crack bridging mechanism is then by far the main operative mechanism in Si_3N_4 on the microscopic scale (Pezzotti *et al.*, 1999a,b).

From the analysis of the bridging stresses measured by Greene *et al.* (2012) in Al_2O_3 and Si_3N_4 using spectroscopy methods, they conclude that spectroscopy methods only yield reliable bridging stress results if a reasonable through thickness volume of material is sampled. While 2.5% of the specimen thickness achieved using fluorescence spectroscopy appears adequate for Al_2O_3 , the 0.1%–0.2% of the sample thickness achieved using Raman spectroscopy for Si_3N_4 appears inadequate.

Calculation of Bridges Stresses From of COD in Vickers Cracks

The measurement of the *R*-curves from the crack tip opening displacement (COD) profile on Vickers indent cracks has some important advantages for determining the intrinsic crack-tip toughness, K_{I0} . These are the ease of producing indentation cracks and analyzing the COD in the microscope, and the fact that the COD measurements can be made on unloaded samples. They are also disadvantages since cracking patterns can vary for different ceramics (different crack shapes, presence of lateral cracking). When the

Fig. 19 Comparison of the bridging relations obtained from the *R*-curve (solid line) and the COD-evaluation (dashed line) in silicon nitride doped with MgO and Y₂O₃ (MgY-SN). Reproduced from Fünfschilling, S., Fett, T., Oberacker, R., *et al.*, 2011. Crack-tip toughness from Vickers crack-tip opening displacements for materials with strongly rising *R*-curves. *J. Am. Ceram. Soc.* 94, 1884–1892 with permission of the American Ceramic Society. All rights reserved.

bridges stresses are determined from COD measurements on Vickers cracks in materials with a very steep *R*-curve, the maximum value does not coincide with that calculated from the *R*-curve. For example, this value calculated from the *R*-curve in silicon nitride is about 1700 MPa at a crack tip distance of less than 2 μm, while from the COD measurements from Vickers cracks the maximal bridging stress value is calculated to be close to 750 MPa (Fig. 19). The main reason for the differences is that the *R*-curve reflects the bridging in the bulk material and COD curves reflect bridging at the surface where the thermal mismatch stresses must disappear in the direction normal to the surface. Consequently, debonding behavior at bridging crystals and frictional bridging effects must drastically be affected (Fünfschilling *et al.*, 2011).

R-Curve and Strength

Many engineering ceramics present *R*-curve behavior with fracture toughness increasing with crack extension. As a consequence, they show “flaw tolerance”, that is, the strength becomes less sensitive to initial flaw size relative to some conventional ceramics with single fracture toughness. The relation between initial flaw size, *R*-curve, and strength becomes not straightforward. In important technical strong ceramics, the strength depends of the first microns of crack extension of the *R*-curve, but the characterization of this part of the curve is challenging with macroscopic cracks. One reason is that if cracks are several millimeters in length significant toughening may be associated with the precrack. A second reason is that, if the cracks used for *R*-curve start from blunt notches they are overdriven and an unstable jump in crack length occurs until the crack extends more than the notch root radius. The result is that *R*-curves often begin at stress-intensity values well above the intrinsic toughness of single grains (Gilbert *et al.*, 2005). If the initial crack is of the order of the grain size, there are other factors that complicate the measurement of the initial part of the *R*-curve as, for example, the presence of local residual stresses from thermal expansion mismatch and the tendency towards a local not straight microcrack path (Kruzic *et al.*, 2008). All these effects are especially important in bridging ceramics such as Si₃N₄ in which the *R*-curves rise initially very steeply at short crack lengths relative to other bridging ceramics (Al₂O₃, SiC) giving them their exceptional strength and relative insensitivity to flaw size.

The relation between strength and initial part of the *R*-curve can be illustrated examining MgO–La₂O₃- and MgO–Lu₂O₃-doped ceramics (Kruzic *et al.*, 2008). The higher ionic radius of La with respect to Lu induces weaker grain-boundary adhesion and higher toughness for long cracks. However, the Lu-doped Si₃N₄ has higher strength, which can be explained by its steeper initial *R*-curve although its saturation toughness is lower than the La-doped material (Fig. 20).

R-Curve in Ceramic Laminates

Monolithic ceramics without *R*-curve behavior can still show this effect when they are processed as laminates composed by at least two different monolithic ceramics. A laminate can be formed by sintering layers of monolithic A with thickness t_A and monolithic

Fig. 20 Early *R*-curves for Lu and La-doped silicon nitrides. For small initial flaw sizes, a_i , the initial part of the *R*-curve determines the strength. K_{app} is plotted for $a_i = 540 \mu\text{m}$ and an applied stress of 510 MPa which is the predicted fracture strength for the La-doped Si_3N_4 at that flaw size. Reproduced from Kruzic, J.J., Satet, R.L., Hoffmann, M.J., Cannon, R.M., Ritchie, R.O., 2008. B layers with thickness t_B . Ceramic laminates can be classified in two types according to the interface between layers. For reviews on processing and mechanical characterization of laminates see, for example, Chan (1997), Minatto *et al.* (2014), Lube (2007), Sestakova *et al.* (2011) and Bermejo and Deluca (2013).

Those laminates with weak interfaces are inspired by biological structures such as mollusc shells formed by thin layers of calcium carbonate and tough polymers arranged in a hierarchical structure (Deville *et al.*, 2006). In the laboratory, the laminates with weak interfaces can be produced, for example, by combining thin layers with high porosity with thicker layers with low porosity (Blanks *et al.*, 1998; Davis *et al.*, 2000). In this example, neither chemical incompatibility nor differential shrinkage mismatch are produced so that residual stresses in the layers are avoided.

When a crack grows in a strong layer perpendicularly to a weak interface, it is kinked into the interface or weak layer and it is forced to grow as a delaminating crack. Eventually, the crack enters the strong layer and grows until arriving to the next weak interface where kinks again inducing delamination. This process is repeated again until final fracture.

The analysis of fracture of weak interface laminates is based on the criterion for crack deflection at an interface between two elastically dissimilar materials (He and Hutchinson, 1989). From this analysis, it comes out that the main requirements for designing strong laminates with weak interfaces are: (1) a high strength of the lamina of the A layer, (2) a high toughness of the very thin B-layer (or interface) to enhance the energy consumption for the propagation of the delamination cracks, but low enough to guarantee crack deflection, (3) for the same reason as (2), a low Young's modulus of the weak B-layers.

In terms of *R*-curve, it is more interesting to analyze laminates composed by two high strength monolithic ceramics, A and B, with different elastic and thermal properties. High residual biaxial stresses can arise in the laminate after sintering because of differential shrinkage if a strong interface is formed between layers.

To simplify the analysis of the *R*-curve of ceramic laminates with strong interfaces, the case of only two materials A and B will be considered together with a number of simplifying assumptions: (1) the laminate is described as an infinite plate and the influence of free surfaces is neglected; (2) the layer architecture is periodical and is mirror symmetrical with respect to the mid plane of the laminate; (3) the coefficients of thermal expansion of A and B are different, but the elastic properties are similar; (4) the thickness of the laminate is infinite. Under these assumptions, it can be shown (Oel and Fréchet, 1967) that the magnitude of the residual stresses, σ_A and σ_B , in an infinite thick laminate are approximately related by:

$$\frac{\sigma_A}{\sigma_B} = -\frac{t_B}{t_A} \quad (36)$$

To study the *R*-curve in these laminates we shall consider a short straight through-thickness edge crack of length a perpendicular to the layers (see Fig. 21). It is assumed that the applied stress is uniaxial and homogenous and perpendicular to the crack. The effect of the residual stress in the layers can be treated as an external stress which acts in addition to the applied stress. The condition for the initiation of fracture is then

$$K_{app} = K_C - K_{res}(a) \equiv K_R(a) \quad (37)$$

Fig. 21 Periodic multilayer architecture of alternating layers of materials A and B of thickness t_A and t_B respectively with a through-thickness edge crack of length a propagating perpendicular to the layers.

Fig. 22 Apparent *R*-curves ECS laminates characterized by $E = 390$ GPa, $\nu = 0.22$ and $\Delta\alpha = 1 \cdot 10^{-6} \text{ K}^{-1}$. $\sigma_0 = 590$ MPa and $t_A + t_B = 1$ mm. Two different values of t_B/t_A are considered: $t_B/t_A = 7/3$ (ECS1) and $9/1$ (ECS2). Reproduced from Bermejo, R., Deluca, M., 2013. Fracture mechanics. In: Handbook of Advanced Ceramics, second ed. Elsevier, pp. 733–751 with permission from Elsevier. All rights reserved.

where K_C is the fracture toughness of the monolithic ceramic and $K_{res}(a)$ is the stress intensity factor due to the residual stress which is negative for a compressive residual stress and positive for a tensile residual stress. For a layer with compressive residual stresses the effect is similar to the presence of crack tip shielding as described in previous sections, but, in this case, it is originated by the architecture and different expansion coefficients of the layers and not by the microstructure of both monolithic layers. If the residual stress is tensile, K_R will decrease with increasing crack extension. Finally, K_{app} is given by Eq. (1) with Y being constant and equal to 1.12 because of the assumption of infinite plate thickness.

The description of the crack shielding caused by residual stresses is simplified under the assumption that the elastic properties of materials A and B are equal since then $K_{res}(a)$ can be then determined using the weight function method (see Section “Stress Intensity Factor from Bridging Interactions”). The weight function method gives a very good approximation of the *R*-curve for laminates made of materials with similar elastic properties (E -moduli ratio less than 2). This condition is satisfied within the most common range of ceramic materials.

The *R*-curve that results depends on whether the external layer of the laminate is under compressive stresses (ECS) or tensile stresses (ICS). To illustrate the magnitude of the *R*-curve in ECS laminates we refer to the examples given in Sestakova et al. (2011) and Bermejo and Deluca (2013) where the values taken for the elastic properties of A and B materials are $E = 390$ GPa, $\nu = 0.22$ and $\Delta\alpha = 1 \cdot 10^{-6} \text{ K}^{-1}$ (the difference in thermal expansion coefficient). A new parameter σ_0 is defined as $\sigma_0 \equiv \sigma_A - \sigma_B$ and in the present example equals 590 MPa with $t_A + t_B = 1$ mm. The *R*-curves that result are shown in Fig. 22 for two ECS laminates with different t_B/t_A ratios, 7/3 (ECS1) and 9/1 (ECS2). In the thicker external A-layer (ECS2) the residual stress is lower and the corresponding *R*-curve at the interface reaches a lower value than in the thinner A-layer (ECS1) for which the residual compressive stress is higher.

From the curves shown in Fig. 22 for the first two layers, the maximum shielding is achieved at the first A/B interface, that is, when the crack length is equal to t_A . This peak value can be written as (Sestakova et al., 2011; Bermejo and Deluca, 2013):

$$K_{R, peak} = K_C - 1.12\sqrt{\pi t_A} \sigma_0 \frac{t_B}{t_A + t_B} \quad (38)$$

Fig. 23 Apparent toughness and strength in a typical ICS-laminate versus the crack size parameter. The curve corresponds to a laminate characterized by $\sigma_0 = +590$ MPa and $t_A + t_B = 1$ mm, whereas $t_B/t_A = 4/1$, $\sigma_A = 118$ MPa and $\sigma_B = -472$ MPa. Reproduced from Bermejo, R., Deluca, M., 2013. Fracture mechanics. In: Handbook of Advanced Ceramics, second ed. Elsevier, pp. 733–751 with permission from Elsevier. All rights reserved.

From this expression it can be shown that under the condition of $t_A + t_B = \text{constant}$, the maximum value of the R -curve is reached for $t_B/t_A = 2$ and this maximum increases with the value of $t_A + t_B$.

To examine the influence of the R -curves on the strength, we shall assume that main cracks are in the outer layer with dimensions in the usual range so that $1.12\sqrt{\pi a}$ is in the shaded bar of Fig. 22. The application of increasing external stresses induces stress intensity factors represented by the lines 1–4. It can be appreciated that the stress needed for fracture from the largest crack in the shaded area is given by the slope of line 3 for ECS1. By contrast, for the ECS2 laminate the fracture stress for the largest flaw in the same shaded area is given by the slope of line 4. We can see then that the laminate with the higher toughness is not the stronger one.

For ICS-laminates a similar analysis as for ECS can be carried out with the same simplifying assumptions as before. The apparent R -curve can be determined by the weight function method neglecting the difference in the elastic properties of the layers. Now the presence of a tensile residual stress in the outer A-layer produces a decreasing R -curve in this layer, which increases in the B-layer because of the presence of the compressive residual stress. The peak of the R -curve is reached in this case when $a = t_A + t_B$. The determination of this peak value in ICS laminates by the weight function method gives now a more complex expression. However, calculations show that, for $t_A + t_B = \text{constant}$, the maximum of the R -curve is achieved for $t_B/t_A = 0.25$. (Sestakova *et al.*, 2011; Bermejo and Deluca, 2013).

As can be seen in Fig. 23, the crack behavior depends on the crack size. For very small cracks in region I unstable crack propagation will take place (line 1) leading to catastrophic failure; however, cracks in region II will first pop in at the intersection of line 3 with the decreasing R -curve and then stop when the increasing part of the R -curve in B-layer is reached. If the stress is further increased, stable crack growth up to a length equal to $t_A + t_B$ occurs. Line 2 corresponds to the stress, where these cracks become unstable again and where catastrophic failure occurs. Line 2 determines a threshold for the strength of the laminate, which is given by:

$$\sigma_{th} = \frac{K_{R, peak}}{1.12\sqrt{\pi(t_A + t_B)}} \quad (39)$$

Finally, it should be noticed that although residual stresses are essential for increasing toughness, they can also induce a negative influence in the mechanical properties since they can also damage the sintered laminate in the form of tunnels cracks that may appear at the surface of the tensile layers if the residual stress is too high. Another type of defect are edge cracks which appear at the free edges of compression layers. These cracks compromise the strength and fracture toughness so that they should be taken into account in the design of ceramic laminates.

Subcritical Crack Growth: Basic Relations and Experimental Evaluation

Malika Saâdaoui, Mohammed V University, Rabat, Morocco

Basic Relations

Crack Growth Law

Subcritical crack growth (SCCG), also called slow crack growth, occurs at a stress intensity factor below the fracture toughness, particularly in humid environment. It is governed by the stress intensity factor, K_I (in mode I loading), which is linked by a unique relation to the crack growth rate, v . For most ceramics and glasses, it is attributed to stress assisted corrosion at a crack tip, or any pre-existing defect in the material. This is the result of the combined effect of high stresses at the crack tip and the presence of water molecules (reducing surface energy at the crack tip) that induce crack propagation in a subcritical manner (Wiederhorn, 1967; Wiederhorn, 1974; Lawn, 1975; Michalske, 1983). As a general trend, SCCG is described on the basis of a crack velocity versus stress intensity factor (v - K_I) curve representation of which is shown in Fig. 1 in a log-log plot.

Below a threshold value, K_{I0} , there is typically negligible or no crack growth, which determines a safety range of the material use. Just beyond K_{I0} , three stages of crack propagation attributed to distinct mechanisms can be distinguished. In region I corresponding to low crack velocities, crack propagation is controlled by stress-assisted reaction kinetics at the crack tip. Region II corresponding to a constant crack velocity (plateau value), is controlled by the rate of transport of reactive species to crack tip. A slight ascending slope can also be observed in this region. Increasing K_I leads to high crack growth rates (region III) followed by unstable fracture, independent of the environment and controlled by the fracture toughness, K_{Ic} . Region I is of primary importance as it corresponds to the longest regime. In this region, the crack growth rate, v , is given by an empirical power-law relation (Wiederhorn, 1974; Munz and Fett, 1999) for most ceramics and glasses:

$$v = \frac{da}{dt} = AK_I^n = A^* \left(\frac{K_I}{K_{Ic}} \right)^n \quad (1)$$

where a is the crack size and t is time. A , A^* and n are parameters depending on the material, the temperature and the environment. Accurate determination of these parameters leads to lifetime prediction for ceramic components. n is known as the subcritical crack growth susceptibility coefficient. Its value is usually in the range 10–100 and the threshold K_{I0} may be around half the fracture toughness (Anglada, 2017). Comparison of the sensitivity to SCCG can be made using a normalized v - K_I/K_{Ic} diagram illustrated in Fig. 2 for different materials. The higher the slope of the diagram, i.e., the higher the K_{I0}/K_{Ic} ratio, the lower the sensitivity to SCCG by stress assisted corrosion. In this representation, very fine microstructures are considered to avoid microstructural effects (R-curve effects) which will be discussed below. It appears that the sensitivity to SCCG is strongly linked to the ionic fraction of the bond (Fig. 3): the higher the ionic fraction, the higher the intrinsic susceptibility to SCCG.

Glasses and oxide ceramics are particularly sensitive to SCCG as water molecules align to the cations at the crack tip surface, creating hydrogen bonding. An illustration of this reaction is given in Fig. 4 for zirconia. Reaction steps at the crack tip involve: (1) adsorption of water to Zr-O bond, (2) reaction involving simultaneous proton and electron transfer, and (3) formation of surface hydroxyls (De Aza et al., 2002).

Lifetimes Prediction

Under arbitrarily time-dependent stresses $\sigma(t)$, a general lifetime relation is obtained by integration of (1) considering the expression of the stress intensity factor ($K_I = \sigma Y(\pi a)^{1/2}$, where Y is a geometrical factor) (Munz and Fett, 1999).

$$\int_0^{t_f} \sigma(t)^n dt = B \sigma_c^{n-2} \left[1 - \left(\frac{\sigma_f}{\sigma_c} \right)^{n-2} \right] \quad (2)$$

B is related to the factor A in Eq. (1) by:

$$B = \frac{2}{AY^2(n-2)} K_{Ic}^{2-n} \quad (3)$$

t_f is time of fracture, (i.e., the time required for a flaw to grow from an initial length to the critical length for catastrophic crack propagation), σ_f is the fracture strength and σ_c is the inert strength (i.e., the strength in the absence of SCCG in an inert environment). Generally, $\sigma^{n-2} \ll \sigma_c^{n-2}$, and Eq. (2) can be simplified as follows:

$$\int_0^{t_f} \sigma(t)^n dt = B \sigma_c^{n-2} \quad (4)$$

Fig. 1 Schematic of typical ν - K_I curve for glasses and ceramics. K_{I0} is the threshold of crack growth and K_{Ic} the fracture toughness.

Fig. 2 Sensitivity to SCCG for different materials. From Chevalier, J., Fantozzi, G., 2005. Slow crack propagation in ceramics at the nano- and micro-scale: Effect of microstructure. In: Bradt, R.C., Munz, D., Sakai, M., White, K.W. (Eds.), *Fracture Mechanics of Ceramics*, vol. 14. New York: Springer, pp. 173–190.

Fig. 3 Effect of the ionic fraction of the bond on the sensitivity to SCCG. From Chevalier, J., Deville, S., Fantozzi, G., *et al.*, 2005. Nanostructured ceramic oxides with a slow crack growth resistance close to covalent materials. *Nanoletters* 7, 1297–1301.

Under static loading (i.e., σ (t) constant), it becomes:

$$t_f = B\sigma_c^{n-2} \sigma^{-n} \left[1 - \left(\frac{\sigma}{\sigma_c} \right)^{n-2} \right] \quad (5)$$

Fig. 4 Schematic representation of the reaction between water and Zr-O-Zr bonds at the crack tip. From De Aza, A.H., Chevalier, J., Fantozzi, G., Schehl, M., Torrecillas, R., 2002. Crack growth resistance of alumina, zirconia and zirconia toughened alumina ceramics for joint prostheses. *Biomaterials*, 23, 937–945.

Due to the high exponent n for glass and ceramic materials, the static lifetimes depend strongly on the applied stress. For long times, (5) can be simplified to:

$$t_f = B\sigma_c^{n-2} \sigma^{-n} \quad (6)$$

Direct Methods to Determine SCCG Parameters

Subcritical crack growth data can be obtained by direct methods, where crack velocity of macrocracks in the order of several mm is measured as a function of the stress intensity factor. The most common are double torsion (DT) (Evans, 1972; Williams and Evans, 1973; Fuller, 1979; Tait *et al.*, 1987), and double cantilever beam (DCB) (Freiman *et al.*, 1973; Champomier, 1979; Wiederhorn, 1974) as they allow stable crack growth which facilitates data acquisition.

Double Torsion Method

Specimen and loading configuration

The double torsion specimen consists of a plate containing a macrocrack, loaded symmetrically in bending to produce torsional deformation in the two plate halves (Fig. 5). An initial sharp crack is generally introduced by loading the specimen at a slow displacement rate. Sometimes, a groove is introduced along the length of the test specimen in order to control the crack path. However, it is not recommended as it leads to complicated stress field, the effects of which are not well understood. Crack path can be controlled without groove if the test specimen and the fixture are carefully aligned (Chevalier *et al.*, 1996).

Stress intensity factor

The determination of K_I is based on a compliance analysis considering that the deflection under the load-point, u , is caused by the elastic torsion of the two identical rectangular bars fixed at the crack-tip (Williams and Evans, 1973; Outwater *et al.*, 1974). Experimentally, it has been found for several materials that the compliance, C , defined as the ratio of load point displacement, u , to the applied load, P , varies linearly with the crack length a :

$$C = \frac{u}{P} = \alpha a + \beta \quad (7)$$

α and β are constants depending on the material properties.

For an applied load, P , the energy release rate, G , which represents the driving force for failure, is given by the following expression:

$$G = \frac{P^2}{2t} \left(\frac{dC}{da} \right) \quad (8)$$

where da is the increment of crack extension and t the thickness of the specimen.

Following Eq. (7), it becomes:

$$G = \frac{\alpha P^2}{2t} \quad (9)$$

Fig. 5 Representation of the double torsion (DT) specimen.

For plane stress, the stress intensity factor K_I can be determined from:

$$K_I = \sqrt{2\mu(1+\nu)G} \quad (10)$$

where ν is the Poisson's ratio, and μ the elastic shear modulus.

Theoretical analysis of the compliance of the DT specimen (Williams and Evans, 1973) allows determination of α and finally the stress intensity factor as a linear function of load:

$$K_I = HP \quad (11)$$

with

$$H = \frac{W_m}{t^2} \left(\frac{3(1+\nu)}{W\Psi} \right)^{1/2} \quad (12)$$

where W and W_m are the width of the specimen and the moment arm respectively (Fig. 5), and $\psi(t/W)$ is a calibrating factor.

In the case of grooved DT specimens, the effective thickness, taking into account the groove depth, must be considered in the expression of K_I (Munz and Fett, 1999). It is to note that in this analysis, the stress intensity factor is independent of the crack length, which makes the DT testing very attractive. However it was found that the stress intensity factor could be a function of the crack length (Pletka and Wiederhorn, 1982; Chevalier *et al.*, 1996) and corrected expressions have been proposed to take into account this variation (Chevalier *et al.*, 1996; Ciccotti *et al.*, 2000; Shyam and Lara-Curzio, 2006; Becker *et al.*, 2011). This was particularly the case for alumina and zirconia materials for which the following corrected expression have been proposed (Chevalier *et al.*, 1996):

$$K_{I\text{cor}} = K_I(a/a_0)^{m/n} \quad (13)$$

where K_I is given by Eq. (11), a_0 is the notch length, $m = 6$ and $k = 32$ are constants for the test specimen geometry and the materials considered.

Crack growth rate

The crack growth rate during the double torsion test can be determined using three different methods: the constant loading test (Mckinney and Smith, 1973), the load relaxation and the constant displacement rate methods (Evans, 1972).

Constant loading test

In the constant loading tests, the sample is subjected to static loads for different durations and the crack growth rates are directly calculated as the ratio of the measured crack increment to loading time. This method allows to measure low velocities by applying the load over a long period of time.

Load relaxation test

In the relaxation test (Williams and Evans, 1973), the specimen is quickly loaded to just below the expected fracture load P_c (typically 90%–95% P_c), then the displacement of the loading point is kept constant during the experiment. The crack growth rate ($v = da/dt$) is determined assigning the load relaxation to the crack propagation. The time derivative of Eq. (7) leads to:

$$\frac{du}{dt} = (\alpha a + \beta) \frac{dP}{dt} + P\alpha \frac{da}{dt} \quad (14)$$

Introducing the load at the beginning or its final value at the end of the test and their associated crack lengths, it comes (u being constant in Eq. (7)):

$$P(\alpha a + \beta) = P_{i,f}(\alpha a_{i,f} + \beta) \quad (15)$$

where subscripts i and f denote reference measurements taken at the beginning or at the end of the test.

Considering Eq. (14), the crack growth rate can be determined from the instantaneous load, the corresponding load relaxation rate, and the initial or the final values of the load and the crack length as:

Fig. 6 Double-cantilever beam (DCB): (a) specimen with constant load, (b) specimen with constant moment, (c) modified tapered DCB specimen.

$$v(t) = \frac{da}{dt} = -\phi \frac{P_{i,f}}{P^2(t)} \left(a_{i,f} + \frac{\beta}{\alpha} \right) \left(\frac{dP}{dt} \right) \quad (16)$$

In practice, the constants α and β are obtained from a compliance calibration curve.

$\phi = t(da^2 + t^2)^{1/2}$ is a correction factor (Evans, 1972) to take into account the inclination of the crack front generally observed in DT specimens (Fig. 5).

Constant displacement rate method

In this method, the specimen is loaded at a constant displacement rate $\dot{u} = du/dt$. A steady state value of the load P (i.e., $dP/dt = 0$) is reached after a transient regime, which allows to calculate the crack growth from Eq. (14):

$$v = \frac{da}{dt} = \frac{\dot{u}}{P\alpha} \quad (17)$$

The whole v - K_I curve can be determined by performing tests at different values of the displacement rate, $\dot{u}$.

The principle advantage of the DT method is that the whole v - K_I curve can be obtained with a single specimen. Moreover, the possibility of indirect determination of the crack growth is practical for the investigation of the effects of temperature or environment on the v - K_I curve.

In practice, it is recommended to combine the relaxation method suitable for high crack growth rates ($> 10^{-7} \text{ m s}^{-1}$) with one of the two other techniques.

Double Cantilever Beam Method

A standard double cantilever beam (DCB) specimen (Fig. 6(a)) consists of a rectangular bar with a slit, loaded by applying symmetrical opening tensile loads at the ends of the beam. This enables the tensile opening mode (Mode I).

To obtain SCCG parameters, the specimen is subjected to different static loads and the crack extensions are directly measured to obtain the crack growth rates. The stress intensity factor is determined on the basis of analytically corrected compliances and measured crack lengths (Freiman *et al.*, 1973):

$$K_I = \frac{\sqrt{12aP}}{(1-v^2)^{1/2} t h^{3/2}} \left[\left(1 + \frac{\delta}{a} \right)^2 + \frac{1+v}{3} \left(\frac{h}{a} \right)^2 \right]^{1/2} \quad (18)$$

where P is the applied load, h is half the height of the specimen, t its thickness, δ is a characteristic length of the beam ($\delta \approx h/3$) and v is Poisson's ratio.

When grooved DCB specimens are used, t must be replaced by the effective thickness, corresponding to the width of the crack to account for the groove effect.

Modified specimens are also used to obtain a stress intensity factor independent on the crack length (Freiman *et al.*, 1973; Sakai and Bradt, 1993). This can be achieved by applying a constant moment rather than a constant load (Fig. 6(b)) or by using a tapered DCB specimen (Fig. 6(c)).

Fig. 7 Logarithmic plot of the strength versus the crack growth rate for a commercial Alumina. The dashed line corresponds to Eq. (19). From Lube, T., Baierl, R.G.A., 2011. Sub-critical crack growth in alumina – A comparison of different measurement and evaluation methods. *Berg Huettenmaenn Monatsh* 156, 450–456.

Indirect Methods to Determine SCCG Parameters

The crack propagation parameters can also be determined using indirect methods, based on the degradation of strength associated to SCCG (Evans, 1974; Wiederhorn, 1974; Ritter, 1978). These include constant stress (static test) and constant stress-rate (dynamic test) method. These methods present the advantage of being easy to conduct on specimens of very simple shape and do not require the measurement of a crack velocity or a crack length.

Dynamic Tests

In dynamic tests (ASTM C1368, 2006), specimens are loaded, generally in bending configuration under a constant stress rate, $\dot{\sigma}$, until fracture. Integration of Eq. (2) by introducing $d\sigma(t) = \dot{\sigma} t$, gives the following relation between the strength, σ_f , and the loading rate:

$$\sigma_f^{n+1} = B\sigma_c^{n-2} \dot{\sigma} (n+1) \left[1 - \left(\frac{\sigma_f}{\sigma_c} \right)^{n-2} \right] \quad (19)$$

For very high loading rates, σ_f tends towards the inert strength, σ_c , whereas for low loading rates, it follows asymptotically:

$$\sigma_f^{n+1} = B\sigma_c^{n-2} \dot{\sigma} (n+1) \quad (20)$$

The SCCG parameter, n , can be simply determined from the slope $(1/n+1)$ of the $\log(\sigma_f) - \log(\dot{\sigma})$ plot, determined within the validity range of Eq. (20). An example of such plot is displayed for a commercial Alumina (Lube and Baierl, 2011) in Fig. 7, where it can be seen that the effect of the stress rate is important at low stress rates while at very high values, the effect is negligible. The dashed line correspond to Eq. (19) with values of n and B respectively of 33.2 and $16705 \text{ (MPa)}^2 \text{ s}$.

The dynamic test is of short duration and it is easy to conduct with specimens containing natural flaws, similar to those present in structural parts. However, it requires a significant number of specimens and it only gives an average value of the different stages. Even in the case of a single stage, the presence of a threshold value or a too high loading rate could lead to erroneous results (Sudreau *et al.*, 1994).

Static Tests

Standard Procedure

In standard static tests, the specimen are tested under different constant applied loads and the results in terms of time to failure are plotted on a $\log(t_f)$ versus $\log(\sigma)$ diagram and analyzed using the common simplified formula (Eq. (6)) in its logarithmic form (Evans, 1974; Ritter, 1978):

$$\log(t_f) = -n \log(\sigma) + \log(B\sigma_c^{n-2}) \quad (21)$$

A linear regression analysis of this plot, allows to determine n (from the slope $-n$), then B (from the intercept).

Static tests allow measurements down to extremely low velocities as life times are much more influenced by the low crack growth rates than strengths used in dynamic tests. However, owing to the dispersion of the results, a lot of specimens are generally required for a fine analysis and accordingly, the procedure is of long duration.

Fig. 8 Lifetimes distribution under static loading ($\sigma = 270$ MPa), determined for a commercial alumina. From Lube, T., Baierl, R.G.A., 2011. Sub-critical crack growth in alumina – A comparison of different measurement and evaluation methods. *Berg Huettenmaenn Monatsh* 156, 450–456.

Statistical Analysis

Ceramic materials, characterized by small values of Weibull modulus, show a large variability in inert strength (σ_c) and the time to failure (t_f), related to the scatter of the initial flaw sizes. A statistical analysis of the data is thus required for correct evaluation of SCCG parameters (Ritter, 1978; Jakus *et al.*, 1978; Peterlik, 1994; Pfingsten and Glien, 2006). Using the two parameter Weibull analysis (Weibull, 1951), the probability of failure for a given strength or time to failure (which are at equal failure probabilities) is obtained by expressing the inert strength in terms of its failure probability distribution:

$$P = 1 - \exp \left[- \left(\frac{\sigma_c}{\sigma_0} \right)^m \right] \quad (22)$$

where m and σ_0 are the Weibull parameters (respectively the Weibull modulus and the characteristic strength). From Eq. (22) we obtain:

$$\ln \ln \frac{1}{1-P} = m \ln \left(\frac{\sigma_c}{\sigma_0} \right) = m \ln \sigma_c - m \ln \sigma_0 \quad (23)$$

m is given by the slop of a regression line of the plot of this relation.

By using Eq. (6), Eq. (22) can be rewritten as:

$$P = 1 - \exp \left[- \left(\frac{t_f}{t_0} \right)^{m^*} \right] \quad (24)$$

with

$$m^* = \frac{m}{n-2} \quad (25)$$

and

$$t_0 = B \sigma_c^{n-2} \sigma^{-n} \quad (26)$$

m^* is obtained from the slop of linear regression of the logarithmic plot of Eq. (24):

$$\ln \ln \frac{1}{1-P} = m^* \ln t_f + m^* \ln \left(\frac{\sigma^n}{B} \right) - m \ln \sigma_0 \quad (27)$$

then the SCCG exponent, n , is deduced from Eq. (25).

Fig. 8 shows an example of life times distribution determined for a commercial alumina for which, it was found that $m^* = 0.554$ and $n = 32.7$, which is very close to that obtained by the dynamic tests (Lube and Baierl, 2011).

General comments

In the procedures and examples described above, a shape of the ν - K_I curve is presupposed (Eq. (1)) and the tests are performed with samples containing natural flaws. Fett and Munz (1985) have proposed a modified analysis which presents the main advantage of not requiring any prerequisite on the sub-critical crack law. Static tests can also be performed with indentation cracks for which the initial sizes can be measured (Gupta and Jubb, 1981; Fett *et al.*, 1988). Indentation controlled surface cracks allow the determination of the SCCG parameters with a single applied load and a limited number of specimens (Olagnon *et al.*, 1994). They also can be used to evaluate the slow-crack-growth behavior at elevated temperature (Mendiratta and Petrovic, 1978) or to

Fig. 9 Effect of humidity on SCCG in a soda-lime glass. From Wiederhorn, S.M., 1974. Subcritical crack growth in ceramics. In: Bradt, R.C., Hasselman, D.P.H., Lange, F.F. (Eds.), *Fracture Mechanics of Ceramics*. New York: Plenum, pp. 613–646.

determine the threshold stress intensity factor on the basis of the decay of the residual indentation stresses over time (Marx *et al.*, 2004; Garmendia *et al.*, 2011).

Instead of the commonly used bending tests on rectangular bars, the SCCG parameters are increasingly determined using biaxial flexural tests (Krohn *et al.*, 2002; Gonzaga *et al.*, 2011; Bermejo *et al.*, 2013; Bakken *et al.*, 2018) due to their easy use. For example, the ball-on-three-balls test is detailed in (Bermejo, 2020), where a methodology is presented to model the crack growth rate law of brittle materials in various environments.

Typical ν - K_I Curves for Glasses

SCCG behavior of glasses depends on many parameters, the more important of which are composition, environment and temperature (Gy, 2003; Jones, 2008; Ciccotti, 2009). The dependence of these parameters can generally be fitted by the expression (Wiederhorn, 1967):

$$\nu = D \left(\frac{p}{p_0} \right)^{n'} \exp \left(- \frac{\Delta E_a - b K_I}{RT} \right) \quad (28)$$

where p is the partial pressure of the vapor phase in the atmosphere, p_0 is the total atmospheric pressure and R the gas constant; D , n' , ΔE_a and b are adjustable parameters corresponding to the dependence on the glass composition.

The value of the n exponent (Eq. (1)) varies within a wide range, for example between 12 and 50 for silicate glasses (Evans and Wiederhorn, 1974). Fig. 9 illustrates the effect of humidity on SCCG in a soda-lime glass for which the three stages of propagation were observed. Increasing the amount of water in the environment shifts region I towards lower K_I values, without changing the slope n , and region II towards higher crack growth rates.

Fig. 10 shows examples of ν - K_I curves obtained by the DCB method for glasses with different compositions (Wiederhorn and Bolz, 1970). For soda-lime silicate and borosilicate glasses, deviation from Eq. (1) was observed with threshold values respectively of 0.26 MPam^{1/2} and 0.34 MPam^{1/2}. The last value is similar to that obtained from lifetime measurements by Fett *et al.* (1991). The threshold was observed in other glasses for which it was shown that the position of the threshold depends strongly on the pH (Simmons and Freiman, 1981; Gehrke *et al.*, 1991). It was suggested that the effect of the composition on SCCG in glasses have their origin in the nature of the chemical bonding of these materials and the ability of these bonds to resist separation by mechanical and chemical forces (Wiederhorn, 1991). Moreover, Michalske and Bunker (Michalske and Bunker, 1987) proposed that the molecule size affects crack tip reactivity and thus the SCCG behavior of glasses.

The effect of temperature on the ν - K_I curve is shown in Fig. 11 for a soda-lime glass tested in water in which only the stage I was observed (Wiederhorn and Bolz, 1970). Increasing the temperature increases the crack growth rate at a fixed stress intensity factor, as a consequence of the thermal activation of the stress corrosion process having an exponential dependence with the inverse temperature, $1/T$ (Eq. (28)). Such behavior was also observed in a phosphate glass for which the three regions of stress corrosion were observed at ambient temperature (Crichton *et al.*, 1999).

New York: Springer, pp. 173–190.

Characterization and understanding of SCCG of glasses is crucial not only for their applications in bulk form, but also because they are often present at the grain boundaries of polycrystalline ceramics. Their sensitivity to stress-induced corrosion directly affects the subcritical crack-growth behavior of these materials as it was shown for alumina (Barinov *et al.*, 1998; Ramalingam *et al.*, 2011; Bakken *et al.*, 2018) and silicon nitride (Bhatnagar *et al.*, 2000; Jacobs and Chen, 1994).

Typical v - K_I Curves for Polycrystalline Ceramics

Effect of Environment and Temperature

Examples of v - K_I curves with typical pattern of SCCG due to stress corrosion are shown for different environments and temperatures in Fig. 12 for a polycrystalline YTZP zirconia doped with 3 mol% of Y_2O_3 (Chevalier and Fantozzi, 2005). The results show the presence of a threshold under vacuum, water and air conditions, below which no propagation occurs. In water, only the stage I appears and under vacuum or silicon oil where no water molecules are present, only the stage III occurs for a stress intensity factor near K_{IC} . Due to the thermal activation of SCCG (Eq. (28)), increasing the temperature shifts region I towards higher K_I values as for glasses.

Carbides and nitrides, characterized by a low fraction ionic bonding, are relatively insensitive to SCCG at ambient. However, it was shown that they exhibit slow crack propagation at high temperatures (Evans and Lange, 1975; Choi *et al.*, 1998; Lube and Dusza, 2007).

Microstructural Effects

For polycrystalline ceramics, the microstructure plays a major role which requires a careful interpretation on the v - K_I curves obtained experimentally, particularly for reinforced materials for which the crack growth resistance increases with crack growth (R-curve effect). In this case, the crack growth curve is progressively shifted to lower velocities as crack resistance increases. Depending on the crack length measurement with respect to the rising part of the R-curve, either a complete shift or a higher slope can be obtained (Chevalier and Fantozzi, 2005). The most important toughening mechanisms in ceramics are grain bridging and transformation toughening, which act as crack-shielding mechanisms due to closure tractions in the wake of a propagating crack (Knehan *et al.*, 1983; Heuer, 1987; Evans, 1990; Fantozzi and Saâdaoui, 2014). Due to the crack shielding associated with the reinforcement, the effective crack tip stress intensity factor, K_{tip} , corresponding to the driving force for crack growth may be expressed as follow:

$$K_{tip} = K_I - K_{sh} \quad (29)$$

Fig. 14 v - K_I curves of polycrystalline YTZP zirconia ceramics with too different grain sizes (0.3 and 1 μm), compared to that of a zirconia single crystal for which no transformation toughening occurs. From Chevalier, J., Fantozzi, G., 2005. Slow crack propagation in ceramics at the nano- and micro-scale: Effect of microstructure. In: Bradt, R.C., Munz, D., Sakai, M., White, K.W. (Eds.), *Fracture Mechanics Of Ceramics*, vol. 14. New York: Springer, pp. 173–190.

where K_I is the applied stress intensity factor and K_{sh} is the shielding contribution due to the microstructure.

Influence of grain bridging

Grain bridging, occurs in monolithic ceramics, such as alumina (Marshall *et al.*, 1983; Steinbrech *et al.*, 1990; Swanson *et al.*, 1987) and silicon nitride (Li *et al.*, 1992). It arises from elastic and interfacial frictional stresses that act to reduce the crack opening. Its magnitude is controlled by microstructural parameters such as grain size and morphology (aspect ratio). Increasing the shielding effect of bridging during crack propagation, enhances the threshold of crack propagation and the apparent stress intensity factor, K_I (Eq. (29)) during sub-critical crack growth (Ebrahimi *et al.*, 2000; El Attaoui *et al.*, 2005). An example of such effect is illustrated in Fig. 13(a) for alumina with v - K_I curves obtained by the relaxation method under DT loading. The higher the grain size, the higher the slope of stage I and the apparent threshold value K_{I0} , defined as the minimum applied stress intensity factor that leads to measurable crack propagation. This is related to the increase of the shielding effect of grain bridging with the grain size (Chantikul *et al.*, 1990; Kovar *et al.*, 2000). This also explains the convergence of the v - K_I curves at high crack growth rate corresponding to the beginning of the relaxation test from small crack lengths, for which bridging interactions are not yet fully developed.

Crack shielding is an extrinsic mechanism that occurs at the crack wake. Considering the stress intensity factor at the crack tip by the subtraction of the shielding effect (Eq. (29)) leads to an intrinsic v - $K_{I_{tip}}$ curve independent of the grain size and only dependent of the chemical bonds broken at the crack tip (Fig. 13(b)).

It is to not that extrinsic mechanism could not be totally effective for real short cracks. For example, Munz and Fett (1999) showed that a crack velocity decrease could be observed at the beginning of the propagation of small cracks in alumina.

Effect of phase transformation toughening

Transformation toughening which may occur in zirconia based ceramics is due to a stress-induced martensitic transformation of tetragonal zirconia grains or particles to the monoclinic phase ahead of a propagating crack. During crack propagation, the volume increase ($\sim 5\%$) accompanying the transformation, creates compressive stresses that shield the crack tip from the applied stress (Marshall *et al.*, 1983; Hannink *et al.*, 2000). The shielding stress intensity factor is proportional to the applied one (McMeeking and Evans, 1982):

$$K_{sh} = C_{sh} \cdot K_I \quad (30)$$

where C_{sh} is a parameter which increases with the material transformability.

If we assume that the intrinsic mechanism of SCCG is given by:

$$v = A_0 K_{I_{tip}}^n \quad (31)$$

then, the experimentally determined v - K_I law in the presence of transformable zirconia particles is:

$$v = A_0 (1 - C_{sh})^n K_I^n = A K_I^n \quad (32)$$

This means that the effect of transformation toughening on slow crack growth is to shift the v - K_I curve towards high stress intensity factors, preserving the value of the n exponent. This is illustrated in Fig. 14 showing v - K_I curves of polycrystalline YTZP zirconia ceramics with different grain sizes, compared to that of a zirconia single crystal for which crack shielding does not occur. Increasing the grain size leads to a shift of the SCCG curve towards higher stress intensity factors, expressing an increase of crack resistance due to higher transformability. At the same time, the curves run parallel, with a slope corresponding to intrinsic zirconia n exponent (Chevalier and Fantozzi, 2005).

Zirconia-toughened alumina (ZTA) composites show improvement in SCCG resistance, compared to a fine grain alumina or zirconia. This is illustrated in Fig. 15 showing v - K_I curves of two ZTA composites corresponding to different reinforcement

Fig. 15 Comparison of ν - K_I curves for fine grain alumina and zirconia, a microcomposite ZTA and a nanocomposite ZTA. From Chevalier, J., Taddei, P., Gremillard, L., *et al.*, 2011. Reliability assessment in advanced nanocomposite materials for orthopaedic applications. *Journal of the Mechanical Behavior of Biomedical Materials* 4, 303–314.

strategies (Chevalier *et al.*, 2005; De Aza *et al.*, 2003): a micro-composite containing 10 vol% of zirconia with an optimized particles size (100–600 nm) and a nanocomposite containing a small amount (1.7 vol%) of zirconia nanoparticles (< 100 nm). The micro-composite offers two main advantages. Primarily, crack propagation occurs through the alumina matrix which has a lower susceptibility to stress assisted corrosion than zirconia. Second, transformation toughening by zirconia particles shifts the ν - K_I curve towards higher K_I values while preserving the slope of the alumina curve. For the nanocomposite, no transformation toughening occurs, since the particles are too small to transform even at the crack tip. For this material, both the toughness and the threshold are significantly increased. This is attributed to a compressive residual stress field in the alumina matrix, which retards the crack front opening when an external stress is applied. The relative effect of the residual stress intensity factor is higher for lower applied stress intensity factors. Thus, the ν - K_I curve of the nanocomposite exhibits a high slope, close to that of covalent ceramics, (Chevalier *et al.*, 2005), implying a lower sensitivity to delayed failure. It is to note that unlike extrinsic mechanism (as grain bridging or transformation toughening operating at the crack wake), the intrinsic reinforcement by compressive residual stresses operating on a scale smaller than the one of the matrix microstructure, can be applied to real cracks under any loading condition.

Concluding Remarks

In this chapter, the basic relations governing the subcritical crack growth and experimental methods to evaluate this phenomenon in glasses and ceramic materials have been presented. This review is not exhaustive as it is only focused on the most important case of mode I loading, considering a power law relationship between the crack growth rate, ν , and the stress intensity factor, K_I . It has been shown that SCCG parameters, the knowledge of which is crucial for life time prediction for components under loading, can be determined from either crack growth data (direct methods) or from strength data (indirect methods). Both types of methods have proper advantages and drawbacks, and attention should be paid to the interpretation of their experimental results, particularly in the case of polycrystalline ceramics. For these materials, SCCG can be analyzed considering (1) the intrinsic response of the atomic bounds to stress assisted corrosion and (2) the influence of extrinsic microstructural effects which dependent on the amount of reinforcement. Examples of such microstructural effects are given in the case of crack bridging and transformation toughening, but other mechanisms such as micro-cracking and residual stresses may also occur and influence the ν - K_I curves.

Subcritical Crack Growth: Modeling of the v-K Curve in Different Environments

Raul Bermejo, Department of Materials Science, University of Leoben, Leoben, Austria and The Pennsylvania State University, PA, United States

Introduction

Many glasses and ceramic materials suffer for subcritical crack growth (SCCG), which enables the stable growth of cracks under an applied load. At ambient and moderate temperatures it is probably the most important damage mechanism for these materials (Gurney, 1947; Wiederhorn, 1967, 1974; Evans, 1974; Danzer, 1993; EN 843-3, 1996; Danzer *et al.*, 2008). It causes a reduction of strength with time under load and, as a consequence, a significant reduction in the load bearing capability of glass- and ceramic-based (brittle) components. SCCG has been recognized as an important limiting factor for their reliability and lifetime. SCCG is strongly promoted by environments with high moisture content (Wiederhorn, 1974) and by elevated temperatures. The basic aspects of this phenomenon are discussed in detail by Saadaoui (2020).

In terms of linear elastic fracture mechanics, cracks may propagate (with a certain velocity, v) for an applied stress intensity factor, $K_I = \sigma Y \sqrt{\pi a}$, lower than the fracture toughness of the material, K_{Ic} (Munz and Fett, 1999). σ is the tensile stress applied perpendicular to the crack plane, Y a geometric factor and a the size of the crack. For most ceramics and glasses, the crack growth rate, v , in the technically relevant velocity region (namely between 10^{-12} and 10^{-5} m s $^{-1}$), also defined as Region I (*reaction-rate controlled region*, see (Wiederhorn, 1974)) can be described by the empirical power-law relation (Wiederhorn, 1967; Evans, 1974):

$$v = \frac{da}{dt} = v_0 \cdot \left(\frac{K_I}{K_{Ic}} \right)^n \quad (1)$$

where t is the time, n is the SCCG exponent and v_0 is a material constant (i.e., critical crack growth velocity) for the particular testing conditions (e.g., environment, temperature). Depending on the crack growth rate and testing conditions different mechanisms of SCCG may take place, which are ascribed to different slopes in a double log plot of the v - K_I curve (Wiederhorn, 1967). Many different ideas on mechanisms for SCCG can be found in the literature, which range from thermally assisted breaking of bonds at the crack tip (Schoeck, 1990), stress enhanced corrosion (Wiederhorn, 1974), hydrolysis of silica bonds to diffusion of water within the crack or the development of a diffusion zone around the crack tip which causes a decrease of the fracture toughness (Wiederhorn *et al.*, 2011). In general the parameter n is used as an indicator for the mechanism but a clear understanding of the physical principles of SCCG is still lacking (Freiman *et al.*, 2009). Among the different models of crack growth, a direct chemical attack of the environment on the crack tip seems to have the strongest experimental support (Michalske and Freiman, 1983) – at least in silicate containing materials. Note that in the regime I very high values of the SCCG exponent n (e.g., around 30) are often reported in the literature (Munz and Fett, 1999). In regime III these values may even become much larger (around 200).

In order to obtain crack propagation data, and thus assess the susceptibility of a material to SCCG, both direct and indirect methods may be employed (Wiederhorn, 1974). With direct methods the crack velocity is measured as a function of the stress intensity factor by direct observation of the crack growth increment on fracture mechanics type specimens (e.g., double cantilever specimen, double torsion specimen) having long cracks. With indirect methods the growth of internal defects (which are described as cracks) causes a degradation of strength. One indirect method which is already standardized is based on strength measurements at different stress rates in a given environment (Fett and Munz, 1990). The different stress rates cause different testing times. In longer lasting tests more time for the crack growth exists and the strength is reduced. This is used to determine the underlying crack growth parameters. It can be assumed that for design purposes the indirect methods deliver more relevant data than direct methods, since they are based on the behavior of real small material defects (which are typical fracture origins in components) and not on artificially made long cracks.

The strength of glasses and ceramics scatter. This is caused by the fact that in each smooth specimen the size of the fracture origin is different, as described by the Weibull theory (Danzer, 1992; Danzer *et al.*, 2001; Danzer, 2006). This large scatter of strength data in combination with the high values of the SCCG exponent makes the measurement laborious. The reliable measurement of a characteristic (or mean) strength needs the testing of many specimens. Several sets of tests at different loading rates have to be employed.

This problem becomes even worse if the testing procedure is not very accurate. The frequently used strength tests for glasses and ceramics (e.g., flexural beam tests or ring on ring tests) are not very precise and measurement uncertainties up to 10% (and even more for small specimens) have been reported (Lube *et al.*, 1997). This makes the determination of a high SCCG exponent even more difficult and the requirement of large data sets even stronger (Bermejo *et al.*, 2012b). For these reasons a much more precise biaxial strength testing method – the ball on three balls test – is proposed in this chapter, which may reduce the number of specimens needed for an accurate measurement dramatically. Another advantage of the B3B test is that the testing is easy and quick to perform.

As an example for the advantages of the use of the ball on three balls test to determine SCCG parameters, the mechanical room temperature strength of a glass-ceramic composite was evaluated to characterize the sub-critical crack growth behavior in this

Fig. 1 (a) Schematic of the ball-on-three-balls testing jig; (b) stress distribution in a plate during biaxial loading. The maximal stress is concentrated in the center of the specimen.

material. Different loading conditions (i.e., from 0.01 to 200 MPa s⁻¹) and environments (i.e., water, air and silicone oil) with low and high relative humidity respectively were selected aiming to reproduce possible loading scenarios during service. Measurement of inert strength was attempted in argon at a very high stress rate. Based on the experimental strength results a model for the SCCG was derived for low and high humidity testing conditions using a double and a single power-law v-K relation, respectively, which could characterize the crack propagation behavior in different environments.

Experimental Evidence of Slow Crack Growth

Reference Material and Geometry

The substrate (glass-ceramic) employed to fabricate the LTCC specimens of study is made of approx. 50% of Al₂O₃ as filler and 50% of several glasses containing Ca, Na, Si, K, B, and Al, where the crystallization degree after sintering exceeds 90%. Microstructural characterization of the bulk material can be found elsewhere (Bermejo *et al.*, 2013). For the biaxial strength measurements samples of “as-received” rectangular plate specimens of dimension ca. 11.0 × 9.6 × 0.4 mm³ were used. For statistical significance, between 10 and 30 specimens were tested for each condition.

Experimental Evaluation of Biaxial Strength

The biaxial strength (maximum failure stress) was determined using the ball-on-three-balls test. The specimen was symmetrically supported by three balls on one side and loaded by a fourth ball on the opposite face (see Fig. 1). The loading balls had a radius of 4 mm resulting in a support radius of ~4.6 mm. A pre-load of 7 N was applied to hold the specimen in the fixture. More details on the testing methodology can be found in previous publications (Börger *et al.*, 2002, 2004; Danzer *et al.*, 2006, 2007). The tests were conducted under displacement control at different cross-head speeds (i.e., 0.0001 mm min⁻¹, 0.001 mm min⁻¹, 0.01 mm min⁻¹, 0.1 mm min⁻¹, and 2 mm min⁻¹) using a universal testing machine (ZWICK Z010, Zwick/Roell, Ulm, Germany). The corresponding stress rates were calculated from the load-displacement curves, ranging from approx. 0.01 MPa s⁻¹ to 200 MPa s⁻¹. The flexural strength was determined in every case from the maximum tensile stress ($\sigma_{\max}$) in the specimen during loading, given by:

$$\sigma_{\max} = f \cdot \frac{P}{d^2} \quad (2)$$

with P [N] the maximum load at failure, d [mm] the plate thickness, and f a dimensionless factor which depends on the geometry of the specimen, the Poisson's ratio of the tested material and details of the load transfer from the jig into the specimen (Danzer *et al.*, 2006). In order to determine the f factor a FEM analysis was performed using ANSYS 14.0 for this geometry (ANSYS, 2011), assuming isotropic elastic properties for the material, giving as a result: $f = 3.3 - 29.9 \cdot (d/L) + 187.8 \cdot (d/L)^2$. Where $L = 11$ mm is the width of the specimen. This factor f is valid for $0.4 < d < 0.5$ mm, for a Poisson ratio $\nu = 0.2$. The factor f for disc-shaped geometries can be accessed at “See Relevant Website section”.

Fig. 2 Weibull diagram of the strength of LTCC specimens tested in argon at $200 \text{ MPa} \cdot \text{s}^{-1}$ (near-inert conditions). The dashed line represents the best fit of the data using the maximum likelihood method.

Biaxial Strength Results in Different Environments

The biaxial strength of LTCC specimens tested under several stressing rates (i.e., 0.01, 0.1, 1, 10, and $200 \text{ MPa} \cdot \text{s}^{-1}$) in different environments (i.e., silicone oil, air with 40% RH, and water) was measured on samples containing between 10 and 30 specimens. The “inert” strength was measured in argon at high speed rate ($200 \text{ MPa} \cdot \text{s}^{-1}$). As an example, the biaxial strength distribution in argon is represented in **Fig. 2** in a Weibull diagram, where the failure stress, σ_f (calculated for every specimen according to Eq. (2)) is plotted versus the probability of failure, F . From the measured failure strength distribution the Weibull parameters, σ_0 and m , were calculated according to EN-843-5 (EN 843-5, 1997). The dashed line represents the best fit of the strength data using the maximum likelihood method. It can be observed that the failure stress values follow a Weibull distribution, which reflects the flaw size distribution in the sample (Danzon, 1992). All ten tested specimens failed at surface flaws located at the tensile surface. Fractographic evidences can be found elsewhere (Bermejo *et al.*, 2013). The characteristic flexural inert strength, σ_{inert} , at room temperature resulted in 460 MPa with a 90% confidence interval (CI) of 449–472 MPa. The Weibull modulus, m , was 26; the limits of the 90% confidence interval for m ranged from 15 to 35. Such a high Weibull modulus indicates a narrow critical flaw size distribution in the tested specimens. Moreover, it also indicates the accuracy of the measurements: (see (Bermejo *et al.*, 2012b) for more details).

In **Fig. 3** the strength data for each set is (log-log) plotted versus the stressing rate, tested in the three environments; the inert strength is also presented for comparison. The characteristic strength and Weibull modulus for each sample as well as the corresponding 90% confidence intervals (error bars in **Fig. 3**) can be found in (Bermejo *et al.*, 2013). From **Fig. 3** different slopes in the stress-stress rate curves can be seen, especially comparing humid environments (e.g., air or water) with dry conditions (i.e., silicone oil). For the cases of air and water, assuming a single power-law to describe the v-K behavior, a SCCG parameter n ranging between 30 and 35 can be obtained (Bermejo *et al.*, 2013). However, the behavior in silicone oil cannot be fitted using a single power-law. Based on the experimental evidences shown in **Fig. 3**, it can be observed how - depending on the stress rate - two different crack growth mechanisms may be taken place. In order to understand the SCCG in dry environments (i.e., silicone oil in our case), a new model for crack growth must be implemented, taking into account different regions in the v-K curve, namely Region I and II. The procedure to model the v-K behavior in different regions, based on strength – stress rate measurements, will be developed in the next section.

Modeling of Subcritical Crack Growth in Different Environments

Modeling the effect of SCCG by using a general crack growth law is based on the Griffith criterion, which predicts that fast fracture occurs when the stress intensity factor is equal or exceeds the fracture toughness of the material:

$$K_I \geq K_{Ic} \quad (3)$$

The stress intensity factor is usually given by

$$K_I = Y \cdot \sigma \cdot \sqrt{\pi \cdot a} \quad (4)$$

while the critical stress intensity factor under inert conditions is defined by:

$$K_{Ic} = Y \cdot \sigma_{\text{inert}} \cdot \sqrt{\pi \cdot a_i} \quad (5)$$

Fig. 3 Characteristic strength as a function of the stressing rate (i.e., from 0.01 to 200 MPa · s⁻¹) in different environments (i.e., oil (□), 40%RH (Δ) and water (○)) presented as log σ₀ vs. log dσ/dt. The inert strength (◇) measured in argon is also shown as reference. The close-up shows the 90% CI of strength of two samples measured in water.

where σ_i is the inert strength and a_i the initial crack length (for this investigation, σ_{inert} was set to 460 MPa and, accordingly, a_i calculated with Eq. (3) yields ~5 μm (assuming Y ~ 1, and K_{Ic} = 2 MPa · m^{1/2})).

By introducing dimensionless quantities, $\hat{K}_I = K_I/K_{Ic}$ and $\hat{\sigma} = \sigma/\sigma_{inert}$, a general evolution equation for the stress intensity factor can be derived:

$$\frac{d\hat{K}_I}{dt} = \frac{\partial \hat{K}_I}{\partial \hat{\sigma}} \times \frac{d\hat{\sigma}}{dt} + \frac{\partial \hat{K}_I}{\partial a} \times \frac{da}{dt} = \hat{K}_I \hat{\sigma} \times \frac{d\hat{\sigma}}{dt} + \frac{\hat{\sigma}^2}{\hat{K}_I} \frac{1}{2a_i} \times \frac{da}{dt} \quad (6)$$

For constant stress rate experiments, as conducted in this investigation (i.e., $\frac{d\hat{\sigma}}{dt} = \dot{\sigma}/\sigma_{inert}$), Eq. (6) reduces to:

$$\frac{d\hat{K}_I}{dt} = \frac{\hat{K}_I}{t} + \frac{1}{\hat{K}_I} \left(\frac{\dot{\sigma}}{\sigma_{inert}} \right) t^2 \frac{1}{2a_{c,0}} \times \frac{da}{dt} \quad (7)$$

Substituting the crack growth rate associated with Region I, i.e., $da/dt = v_0(\hat{K}_I)^n$, into Eq. (7) we obtain a Bernoulli differential equation (i.e., $y'(t) = P(t)y + Q(t)y^n$) on $\hat{K}_I$, with t as independent variable:

$$\frac{d\hat{K}_I}{dt} = \frac{\hat{K}_I}{t} + \left(\frac{\dot{\sigma}}{\sigma_{inert}} \right) t^2 \frac{v_0}{2a_{c,0}} \hat{K}_I^{n-1} \quad (8)$$

This differential equation can be solved even analytically in the case of a single power-law type crack growth behavior, as derived in (Supancic and Schöpf, 2012), resulting in:

$$\hat{K}_I = \frac{\dot{\sigma}}{\sigma_{inert}} \cdot t \cdot \left(1 - \frac{n-2}{n+1} \cdot \frac{v_0}{2a_{inert}} \cdot \left(\frac{\dot{\sigma}}{\sigma_i} \right)^n \cdot t^{n+1} \right)^{-1/(n-2)} \quad (9)$$

The time to fracture, i.e., $t = t_f$ can be calculated from Eq. (9) when $\hat{K}_I$ reaches 1. Then, for a given applied stress rate, $\dot{\sigma}$, the corresponding failure stress value is given by the applied stress at the time of fracture, i.e., $\sigma = \dot{\sigma} \cdot t_f$.

Based on the experimental results in air and in water (i.e., characteristic strength vs. stress rate) Eq. (9) can be solved to best fit the parameters n and v_0 when fracture occurs (i.e. for $\hat{K}_I=1$), for different stress rates (i.e., taking $\dot{\sigma}$ as independent variable). This is plotted in Fig. 4(a) along with the experimental strength data in both environments. The best fit for these data is obtained for $n \sim 35$ and $v_0 \sim 0.5 \text{ m} \cdot \text{s}^{-1}$ for air and $n \sim 31$ and $v_0 \sim 7 \text{ m} \cdot \text{s}^{-1}$ for water. Using these parameters, the v-K curve for this material can be obtained, as shown in Fig. 4(b). It can be inferred from this figure that for a given K_I/K_{Ic} the crack growth rate in water may be more than 2 orders or magnitude larger compared to the rate in ambient air. A direct consequence is a significant reduction of the lifetime of this material in water (see more details in (Bermejo et al., 2013)). We caution the reader that a difference between $n = 35$ and $n = 31$ may not be significant, due to the error in determining the n -exponent from strength – stress rate measurements, as has been analyzed elsewhere (Krautgasser et al., 2017).

In order to model the crack growth behavior in silicone oil, a single power law could not account for the change of slope as found experimentally in the strength–stress rate tests (see Fig. 3). In an attempt to explain and rationalize the crack growth rate, v , as function of the applied stress intensity factor, K , in silicone oil, a double power law was implemented into Eq. (7) for da/dt , according to:

Fig. 4 (a) Characteristic strength as a function of the stress rate (i.e., from 0.01 to 200 MPa s⁻¹) in water (○) and in air (△) presented as log σ_0 vs. log $d\sigma/dt$. The best fit is based on a single power law to describe the SCCG behavior. (b) v-K curve for water and air based on the parameters estimated from the strength-stress rate experiments.

$$v(K_I) = \frac{da}{dt} = \begin{cases} v \cdot \left(\frac{K_I}{K_{Ic}}\right)^n & K_I < K_T \\ v_1 \cdot \left(\frac{K_I}{K_{Ic}}\right)^{n_1} & K_I \geq K_T \end{cases} \quad (10)$$

Eq. (10) introduces five parameters into Eq. (9), i.e., v , n , v_1 , n_1 , and K_T , where four of them are independent parameters. The parameter v_1 can be expressed as: $v_1 = v \cdot (K_T/K_{Ic})^{(n-n_1)}$. The parameter K_T is defined as “transition stress intensity factor” indicating the continuous transition between both crack growth regions, with different SCCG exponents, n and n_1 , respectively.

Now Eq. (7) can be solved in an analogous way and the evolution of $\dot{K}_I$ with time can be obtained. Solving for $\dot{K}_I = 1$, for different stress rates, the parameters v , n , v_1 , n_1 , and K_T can be found which best fit the experimental data in silicone oil. Note that a system of at least four equations is needed to determine the four independent parameters, thus experimental data from four different stress rates are required. Since the region corresponding to low stress rates in oil and in air show the same trend (see Fig. 3) the parameters v and n that describe Region I can be taken as those calculated for ambient air, i.e., $v \sim 0.5$ m s⁻¹ and $n \sim 35$. Thus, the best fit for oil is shown in Fig. 5(a) along with the experimental data. It can be seen how the model tends to a plateau region corresponding to the inert strength, measured in argon (see Fig. 2). However, this has not been measured with experiments yet.

Once the SCCG parameters for silicone oil have been obtained, the v-K curve (as given by Eq. (10)) for LTCC in silicone oil can be built up, as shown in Fig. 5(b). The relationship between log strength vs. log stress rate leads to a kink which is related to the change in the crack growth mechanism occurring in the material during loading. At relatively low stress intensity factors, a *reaction-rate-controlled region* (hydrolysis of Si-O bonds) dominates the crack growth rate (defined as $v = da/dt$ (Wiederhorn, 1967)). At intermediate stress intensity factors the crack growth rate decreases to a level limited by the rate of diffusion of water molecules to the crack tip, and thus a *transport-controlled region* governs the growth rate in the v-K curve (Wiederhorn, 1967). The resulting parameters to describe SCCG of this material in silicon oil may change in a different environment (e.g., argon) and can be also be affected by temperature.

Significance of the Ball-on-Three-Balls Testing Method for SCCG

Several methods can be used to determine the biaxial strength of ceramic-based materials. Recent works on LTCC have employed the ball-on-ring (BOR) test (Dannheim et al., 2004) or the ring-on-ring (ROR) test (Tandon et al., 2007) on bulk specimens, showing the effect of the loading rate and environmental conditions on the mechanical strength. These methods induce a maximal biaxial stress distribution in the center of the specimen and avoid the influence of edge effects. However, it has been shown that, during testing, small geometric inaccuracies (e.g., for the case of “as-sintered” specimens) can lead to an undefined load transfer from the rings to the specimen and thus may cause large uncertainties in the determined strength, as has been observed in (Morrell et al., 1999). Measurement uncertainties (MUs) up to $\pm 10\%$ have been reported. This problem is specially enhanced when testing small specimens (Lube et al., 1997). Other testing methods such as the pin-on-three-balls (POB) technique may be used to avoid

Fig. 5 (a) Characteristic strength as a function of the stressing rate (i.e., from 0.01 to 200 MPa s⁻¹) in water (○), in air (△), in silicone oil (□), and in argon (◇), presented as log σ_0 vs. log $d\sigma/dt$. The best fit in oil is based on a double power law to describe the SCCG behavior. (b) v-K curve for water, air and oil based on the parameters estimated from the strength-stress rate experiments. A “kink” in the oil curve can be observed, indicating different SCCG mechanisms acting at the crack tip.

slight imperfections in the sintered plate (Wachtman *et al.*, 1972), but there remain uncertainties about the loading under a flat-ended pin. Such uncertainties are much reduced when a modified version of this loading configuration, the ball-on-three-balls (B3B) test, is used (Börger *et al.*, 2002, 2004). Therefore, the effect of loading conditions, environment and/or surface features on the strength of such components may be better discerned using the B3B method, as has been reported elsewhere (Bermejo *et al.*, 2009, 2011, 2012a). In Fig. 3 a close-up shows the 90% CI of strength corresponding to two samples tested at different stress rates (i.e., at approx. 1 and 10 MPa s⁻¹). The narrow confidence interval for every testing condition represented by the scatter bars in Fig. 3 is not only a direct consequence of the high Weibull modulus of the material, but also of the high accuracy of the testing method. In a previous work using Monte Carlo simulations, it was demonstrated that MUs of the strength measurement of each specimen might mask the inherent scatter of the material strength (Bermejo *et al.*, 2012b). Measuring the scatter of the strength distribution is only possible if the MUs of the measuring technique are much smaller than the former. Such large MU may be in the range of the scatter of the strength. It has been shown in (Bermejo *et al.*, 2012b) that probably, under these conditions, a Weibull modulus of about $m = 15$ would be determined, whereas the “real” modulus should be $m = 30$ or higher. In our experiments using the B3B technique, the experimental MUs are much less than 1% and an accurate determination of the strength distribution (in particular of the Weibull modulus m) is possible. This testing method largely reduces uncertainties in the load transfer (e.g., due to lack of parallelism between both specimen sides) which might lead to under- or overestimation of the fracture load in the test.

In addition, the use of the B3B method, as inferred from Fig. 3, could allow discerning small differences in strength between samples tested in slightly different environments. Furthermore, as reported in this work, it was possible to observe the similar strength values in oil and in air for low stressing rates, which might have been mistaken by scatter using other testing procedures. In the experimental work presented in this chapter as reference, more than 400 specimens were tested, which also demonstrates the ease and cost efficiency of the B3B test as indirect method, and is therefore recommended for characterizing the SCCG behavior of brittle materials.

Summary and Conclusions

The strength of brittle materials may be strongly affected by the environment and loading conditions in which the material is subject to mechanical stress. This is caused by the subcritical growth of cracks (SCCG) during loading, a mechanism activated by the prolonged presence of humidity at the specimen’s surface loaded under tension.

A methodology based on indirect (biaxial) strength measurements using the Ball-on-three-Balls (B3B) test in distinct environments has been employed to model the subcritical crack growth behavior (v-K curve) in brittle materials. For illustrative purposes, experimental results on a Low Temperature Co-fired Ceramic (i.e., glass-ceramic composite) reference material have been utilized to quantify such effects on strength. Whereas high strength values can be reached during high-rate testing in “quasi-inert” environment (e.g., argon), up to a 50% lower strength values have been measured on specimens immersed in water tested

for longer time periods. In addition, due to the high measurement accuracy of the B3B test, constant stress rate experiments in a relative dry environment (i.e., silicon oil) have shown for the first time evidence of two different crack growth mechanisms taking place during mechanical loading. It is shown how a double power-law for the crack growth rate (i.e., v - K curves) can describe the experimental results in dry environments. This approach might be also employed to describe the SCCG behavior of other functional ceramic-based materials and can be also useful to predict lifetime of components.

This is a reprint of DB Marshall, RHJ Hannink, Ceramics: Transformation Toughening, In: Reference Module in Materials Science and Materials Engineering, Elsevier Inc., 2016, doi:10.1016/B978-0-12-803581-8.03229-X.

Constrained Transformation

Upon cooling from high temperature, pure zirconia undergoes two phase transformations, from cubic (c) to tetragonal (t) crystal structure at $\sim 2367^\circ\text{C}$ and from tetragonal to monoclinic (m) structure at $\sim 1170^\circ\text{C}$. The toughening mechanism, which is similar to that occurring in TRIP (transformation induced plasticity) steels (Zackay *et al.*, 1967), was first reported by Garvie *et al.* (1975). The t–m transformation is martensitic, i.e., diffusionless, and is accompanied by a large shear strain ($\sim 9\%$) and volume increase ($\sim 4\%$). In many practical cases the net shear strain is reduced or eliminated by twinning or by the formation of several variants and is often accompanied by microcracks, which in certain circumstances can lead to an additional fracture toughening contribution (Evans, 1984). Both t and m transformation temperatures can be reduced by alloying with other oxides (e.g., MgO , Y_2O_3 , CaO , Ce_2O_3 , or other rare-earth oxides) that form solid solutions with ZrO_2 .

The t–m transformation temperature can also be reduced by mechanical constraint that opposes the accompanying shape and volume changes. The thermodynamics of the phase transformation for a particle of ZrO_2 embedded in an elastic matrix then involves a balance of two terms: a decrease in chemical free energy accompanying the transformation and an increase in elastic strain energy in both the particle and the matrix. The magnitude of the former increases with decreasing temperature, while the latter is, to first order, independent of temperature. If the magnitude of the strain energy term is sufficiently large, the transformation can be suppressed to cryogenic temperatures. The strain energy can be increased or decreased by the action of a remotely applied stress field (the interaction energy in the analyses of Eshelby (1957)) and the transformation temperature correspondingly changed.

Experimental observations indicate the existence of a size effect in the t–m transformation, which is key to designing toughened microstructures. For a given system of embedded ZrO_2 particles at a given temperature, there exists a critical particle size above which all particles transform spontaneously to the monoclinic phase, and below which the tetragonal phase is stable. The critical particle size decreases with decreasing temperature. Since both of the energy terms mentioned above scale with volume, the existence of a size effect requires either an additional energy term that scales differently with size, or that the transformation be controlled by a nucleation barrier.

Several possibilities exist for energy terms that scale with particle surface area (localized strain energy associated with terminations of twins, as observed in monoclinic particles, and differences in interfacial energies between the matrix and the t or m phases). However, evidence exists for nucleation control in some cases that is dependent on strain concentrations associated either with second phase particles, as in the case of the δ -phase ($\text{Mg}_2\text{Zr}_5\text{O}_{12}$) in magnesia–partial stabilized zirconia (Mg-PSZ) (Hannink *et al.*, 1994) or with the shape of the ZrO_2 particle itself. In the absence of definitive experiments to distinguish these possibilities, the critical conditions for the onset of the t–m transformation remain the least well understood aspect of the transformation and of the associated theoretical predictions of transformation toughening.

Although the martensitic t–m transformation is reversible, hysteresis is observed during temperature cycling, i.e., the martensitic start temperature (M_s) for the forward transformation is lower than the temperature for the reverse transformation (A_s). Hysteresis is also usually observed in experiments involving isothermal stress-induced transformation. Among the potential causes of hysteresis is the formation of microcracks around transformed particles (stabilization by relief of strain energy) or the effect of nucleation steps in the forward and reverse directions.

Toughening Mechanism

Transformation toughening requires a microstructure containing stabilized t- ZrO_2 particles with M_s near or below ambient temperature. The toughening involves the formation of a zone surrounding a growing crack in which the t–m transformation is induced by the concentrated stresses near the crack tip (Figure 1). The transformation strains give rise to closure stresses on the crack, or, in terms of the fracture mechanics formulation, a negative stress intensity factor, K_T , which superimposes on the remotely applied stress intensity factor, K_a , thus opposing further crack growth. In this way the measured fracture toughness is increased by a crack shielding mechanism, while the fundamental brittle bond rupture processes at the crack tip are unchanged.

The contribution of the transform strain to toughening is dependent on the location of the transformed particle relative to the crack tip. For example, in the case of a net dilatational transformation strain, a particle located ahead of the crack (at $\theta < 60^\circ$ in Figure 1(b)) causes additional tensile stresses ahead of the crack tip (and thus reduced toughening), while a particle behind the crack tip (at $\theta > 60^\circ$ in Figure 1(b)) causes compressive stress. This implies that, to achieve effective toughening, the reverse m–t

Figure 1 Schematics of transformation toughening: (a) well-developed transformation zone surrounding crack; (b) effect of individual transformed particle on stresses ahead of crack tip.

Figure 2 R-curve behavior (stress intensity versus crack extension) of two differently aged Mg-PSZ materials, MS (Maximum Strength) and TS (Thermal Shock) grades with the same composition as a function of grain size (Haffman *et al.*, 1993).

transformation should not occur upon removal of the crack-tip stress field, so that a wake of transformed material develops as the crack grows, as indicated in Figure 1(a). A second implication is that the toughening effect for a pre-existing crack will initially increase as the crack grows and the wake develops, before approaching a steady state condition (i.e., R-curve behavior). The effect on R-curve behavior through the influence of heat treatment control of grain size and precipitate size and form is shown for a Mg-PSZ alloy in Figure 2 (Haffman *et al.*, 1993).

The boundary of the transformation zone is determined by the critical stress required to induce the t-m transformation. This stress and, thus, the zone width and the degree of toughening are sensitive to temperature as well as microstructure. The optimum toughening is achieved when the critical stress is small, i.e., when the ambient temperature is above but close to the M_s temperature. This requirement also defines one of the limitations on the application of this toughening mechanism since, although large toughness increases are possible, the mechanism is effective only over a small range of temperatures.

Figure 3 Microstructures of the three most common forms of transformation-toughened ceramics from L to R: Mg-PSZ, Y-TZP (yttria-tetragonal zirconia polycrystals) and ZTA (zirconia-toughened alumina).

Figure 4 Measured strengths and toughnesses for several series of transformation-toughened ceramics (adapted from Swain, 1985).

Microstructures and Properties of Transformation-Toughened Ceramics

While many transformation-toughened microstructures have been investigated, those developed commercially are of three distinct types, **Figure 3**.

- (i) Partially stabilized zirconia (PSZ) consists of coherent $t\text{-ZrO}_2$ precipitates in a matrix of cubic zirconia. The precipitated microstructure is developed by adding a stabilizing solute (MgO , CaO , or Y_2O_3) at concentrations smaller than needed for full stabilization of the cubic phase, sintering at high temperature ($\sim 1600\text{--}1800^\circ\text{C}$) in the cubic phase field, generally resulting in large $c\text{-ZrO}_2$ grains ($\sim 35\text{--}100\ \mu\text{m}$), and heat treating during cooling in the temperature range $\sim 1100\text{--}1500^\circ\text{C}$ to nucleate and grow the precipitates. In Mg-PSZ the precipitates are oblate spheroids with optimum dimensions $\sim 50 \times 200\ \text{nm}$.
- (ii) Tetragonal zirconia polycrystals (TZP) consist of a matrix of fine-grained ($0.1\text{--}1\ \mu\text{m}$), predominantly single-phase $t\text{-ZrO}_2$ with additions of Y_2O_3 , Ce_2O_3 , or other rare-earth oxides. Sintering is carried out in the single-phase $t\text{-ZrO}_2$ field at temperatures in the range $\sim 1300\text{--}1500^\circ\text{C}$ for alloys containing 1.5–3.5 mol.% Y_2O_3 .
- (iii) Zirconia-toughened ceramics (ZTC) consist of $t\text{-ZrO}_2$ particles dispersed (usually intergranularly) in a matrix of another ceramic such as alumina (Al_2O_3) or mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$). A small amount of Y_2O_3 is usually added to the ZrO_2 particles to stabilize the t -phase. The critical particle size is usually between ~ 0.5 and $1\ \mu\text{m}$ depending on the amount of Y_2O_3 additive and the matrix.

Zirconia-toughened materials have the highest strengths ($>2\ \text{GPa}$) and toughnesses ($>15\ \text{MPa m}^{1/2}$) of any polycrystalline ceramics. However, the highest strengths and toughnesses are not found in the same materials (**Figure 4**). In each of the systems

Figure 5 (a) Components of transformation-toughened zirconia (Mg-PSZ and Y-TZP), (b) A series of remotely controlled Z-valves with PSZ liners and valves (courtesy Morgan Technical Ceramics Pty Ltd).

described above the fracture toughness, for given stabilizing solute content, can be varied by adjusting the heat treatment to change the critical stress for transformation, and in most cases the strength is maximum at an intermediate toughness. In the materials with the highest toughness (Mg-PSZ and Ce-TZP) the critical stress for transformation is ~ 500 MPa and transformation zones with widths up to about 1 mm have been observed around well-developed cracks. However, the transformation stress apparently places an upper limit on the strength of the material, for even in the absence of pre-existing cracks, bands of transformation induced by the applied stress lead to failure. The materials with the highest strengths (Y-TZP and zirconia-toughened alumina) have lower toughnesses ($\sim 5\text{--}8$ MPa $\text{m}^{1/2}$) and correspondingly smaller zone widths (< 10 μm).

Additional improvements in properties can be gained by surface grinding. The t-m transformation is induced within a layer near the surface by localized grinding stresses, resulting in a layer of residual compressive stress. The compressive stress inhibits crack initiation and can improve strength, wear resistance, and thermal shock resistance.

Theoretical Understanding of Transformation Toughening

A weight-function method has been used to calculate the reduction in stress intensity factor, K_T , (i.e., the toughness increase) in terms of the distribution of transformation strains surrounding the crack (McMeeking and Evans, 1982). When the transformation strain, e^T , and volume fraction, v_f , of transformed particles are uniform within the zone, K_T is given by

$$K_T = \eta E^* e^T V_f h^{1/2} \quad [1]$$

where E^* is an effective elastic constant, h is a characteristic dimension of the transformed zone, and η is a parameter (with values

in the range ~ 0.22 – 1) that depends on the nature of the transformation strains and the shape of the zone near the crack tip. An equivalent result has been derived from a fracture mechanics energy balance analysis. The result in eqn [1] can be generalized by linear superposition to include effects of nonuniform strain distributions and volume fractions within the transformation zone, which can arise from statistical distributions of M_s temperatures or subcritical transformations.

Experimental measurements indicate that transformation strains generally are nonuniform. Moreover, since ν_f usually decreases monotonically with distance from the crack, the toughening is larger (by a factor of two or more) than it would be for a uniform zone with the same average transformation strain (or ν_f).

In general, the shape of the frontal boundary of the transformation zone and the net transformation strain cannot be predicted *a priori*: both are affected by microstructural characteristics and autocatalytic transformation effects that vary in different systems. Observations indicate that the frontal zone boundary in Mg-PSZ is similar to that defined by a critical hydrostatic stress, while the net strain is close to hydrostatic dilation (i.e., shear strains relieved by twinning). In contrast, the frontal zone in Ce-TZP materials extends in a wedge shape ahead of the crack for a distance about ten times further than in Mg-PSZ.

Applications

Transformation-toughened zirconia has found widespread industrial application as an engineering ceramic, mostly making use of its resistance to wear, chemical inertness, low friction, high hardness and stiffness, and relatively high thermal expansion coefficient (which is closer to metals than those of most other ceramics). Applications of Mg-PSZ include: tooling for the metal forming industry (hot and cold forming dies, can-closure rollers, capstans, draw plugs, and plungers); food processing (homogenizing-pump parts); mineral, gas, and oil treatment (bearings, valves, vortex finders, orifice inserts, spigots, and spools); and the paper, chemical, and manufacturing industries (autoclave nozzles, glue transfer rollers, battery component tooling, and valves). Y-TZP is used for biological applications such as hip-ball replacements, dental implants, industrial cutters, knives, and scissors, as well as golf club inserts. Zirconia-toughened alumina is used for its higher hardness and stiffness in cutting tool tips, high-performance seals and wear parts in engines, and in the mining industry. Typical components made of Mg-PSZ and Y-TZP is shown in **Figures 5(a)** and **(b)**.

Mixed-Mode Fracture and Microstructural Aspects of Crack Propagation

Introduction

Since prehistoric times, ceramic materials have been a constant companion for mankind. It was invented and re-invented in almost all cultures in all continents. Its uses ranged from humble everyday dinnerware to artful Greek and Chinese vases. Ceramic materials, due to their thermal resistance and mechanical properties, were used in many applications, like insulators, refractories for steel fabrication, etc. More recently, ceramic products have been used in extensive and sophisticated applications that include thermal protection for aircraft engines, ultrasonic transducers, multilayer capacitors and applications for dental and medical fields. But, since nothing is perfect, the main disadvantage of ceramic materials is their brittleness, which can cause catastrophic failure of the ceramic component, without prior warning. Despite their brittleness, nowadays, advanced technical ceramics constitute the support of an ample variety of important products. Ceramic compositions, with special characteristics, are continuously being developed to satisfy the demands of new high technology applications, among them: magnetic, optical and high-temperature ceramics, high-strength products, piezoelectrics, dielectrics, semiconductors, spark plugs, heat engines, aerospace applications, solid oxide fuel cells, hip and knee replacements in the human body, dental ceramic prosthetic, etc. To this day, progress continues with developments in nanotechnology and novel processing routes.

Ceramics mechanical behavior have other disadvantages, such as: (1) large scatter of strength caused by the statistical distribution of the flaw size and the flaw location and (2) subcritical crack extension that could cause failure under constant or cyclic loading during the operation of a component. Good performance in mechanical behavior of ceramic components is directly influenced by a large number of factors. Material parameters like composition, microstructure features (phases distribution, pore size, grain size, cracks, surface condition), crystal or amorphous structure, internal strains and specimen shape and size are such factors, but also some environmental parameters like temperature, atmosphere, strain rate, static or cyclic fatigue, type of stress (uniaxial, biaxial, etc.). With so many factors in play, there is a high degree of complexity of the mechanical phenomena of advanced ceramics and glasses and all should be considered when designing the components.

The most important obstacle for a design methodology for a ceramic component is the absence of a definitive mechanical parameter analogous to the yield strength in metals. Many efforts and studies had been dedicated to characterize fracture process of ceramic materials using the fracture strength parameter but, as mentioned before, failure in ceramics depends on many variables. Even with the most detailed and careful design, the ceramic material could fail due to the extension of processing defects such as pores, inclusions, or cracks. Occult, and probably undetectable, defects can lead to catastrophic failure. Therefore, any successful application of ceramics will require a carefully designed strategy for minimizing the occurrence and propagation of cracks that may lead to catastrophic failures. To achieve this, knowledge of how materials fail is a must. The understanding of fracture mechanics plays a main role in the design and the use of ceramic materials, even more where the component would be subjected to significant stresses. Fracture mechanics framework provides a rational, cost effective, approach to the development of a practical design methodology for ceramic materials since it is a strong tool to study: (1) Maximum (or safe) load limit to operate structural components, (2) Safe period of operation under a given load, (3) Detection of possible imminent failure and (4) Post-mortem fracture analysis.

Generally speaking, materials fail in three manners: brittle, quasi-brittle and ductile fractures, with the vast majority of ceramic materials prone to suffer brittle fracture. Early works on fracture mechanics were devoted to the study of brittle fracture in a homogeneous and isotropic body. Griffith's thermodynamic derivations (Griffith, 1920) from Inglis' report (Inglis, 1913) showed a condition for unstable crack growth in brittle materials like glass. Studies by Orowan (1949) provided some insights into the role of cracks and plasticity in fracture. Irwin (1958) developed an important engineering concept for a driving force parameter, called the "stress intensity factor". Williams (1956) and Paris and Erdogan (1963) made contributions for the crack-tip fields under linear elastic mechanics conditions and fatigue, respectively. Later studies led to the development of fracture mechanics approaches for elastic-plastic and fully plastic conditions with Wells' work (crack-tip opening displacement) (Wells, 1961), Rice's study (J integral) (Rice, 1968) and McClintock's research (characterization of the crack driving force under fully plastic conditions) (McClintock *et al.*, 1995). All these developments are covered in conventional texts of fracture mechanics. It is important to highlight that most of the current knowledge about fracture mechanics come from studies on metallic materials, and that the over-emphasis on the differences between structural metals and ceramics had, possibly, delayed the use of ceramics as valuable structural materials. However, since the mid-70s, there has been a substantial research effort to deepening the body of knowledge of the fracture behavior of ceramic materials (Anderson, 2017).

As a model for a material, Irwin's stress intensity factors are especially useful for engineering applications, since it characterizes the stress field near the crack tip. In this model, there are three primary modes that define the orientation of a crack relative to the loading: (1) "the opening mode", where displacement discontinuity is perpendicular to the plane of the crack; (2) "the sliding mode", in which the displacement discontinuity is in the plane and parallel to the direction of the crack; and (3) "the tearing mode", where the displacement discontinuity is perpendicular to the plane of the material and in the plane of the crack (See Fig. 1). The stress concentration at the crack tip is designated by the stress intensity factors K_I , K_{II} and K_{III} . The subscripts represent the direction of load

Fig. 1 Modes of loading respect to crack orientation.

application with respect to the position of the crack. It is also defined the critical stress intensity which indicates when the crack will propagate and lead to fracture, and it is known as the “fracture toughness”. The higher the fracture toughness, the more difficult will be to initiate and propagate a crack (Anderson, 2017). Mode I is the most frequently reported in the literature and stress analysis solutions for K_I for a variety of crack locations within simple geometries have been extensively presented. Also, estimations of K_{Ic} from experimental data for a diversity of materials have been produced.

The theoretical model behind the definition of K_I assumes that the direction of crack growth is known, so that the defining equations (See Fig. 1) could only be useful when the load is applied normal to the crack and in such a way that the crack propagates in a self-similar manner. In practice, nonalignment of loads pertaining to crack orientation is the case, so the crack tip stress field involves the combination of three stress intensity factors (K_I , K_{II} and K_{III}) and it is no longer governed solely by mode I stress loading. Additionally, the direction of crack initiation is unknown and depends on combinations of K_I , K_{II} and K_{III} that satisfy some fracture criteria. Actually, modes II and III do not occur separately, but always in combination with mode I, e.g., I-II, or I-III or I-II-III. Obviously, the understanding and management of the combined modes is more complex than that presented in the studies carried out for mode I, but in the industry, the mixed-mode fracture and the mixed-mode crack growth are recognized more as the rule than as the exception, i.e., the applied loadings usually do not coincide with the orthogonal K_I - K_{II} - K_{III} space. While there are many excellent books and articles about fracture mechanics, just a handful of them deal with the mixed-mode fracture topic, and most present studies made on metals (Anderson, 2017). This is understandable, since many of the more conventional fracture criteria (maximum normal stress, critical stress intensity factor or energy release rate, etc.) that have been successful when applied to simpler crack problems, are inadequate, and often invalid, for more complex situations like those of the mixed-mode fracture process. Since most ceramic structural applications involve a combination of tensile (mode I) and shear (mode II) loading conditions, the knowledge of mixed-mode fracture behavior of ceramics is necessary for furthering the use of these materials in more applications. In this context, the present chapter is based on the published current knowledge for mixed-mode fracture and microstructural issues of crack propagation in ceramics and glasses.

Mixed-Mode Fracture Criteria

The practical importance of fracture mechanics studies relies on the prediction of crack growth, which, in turn, is based on answering two questions: When the crack will start to grow? and What direction will the crack follow?. It is well known, in a homogeneous isotropic material, crack propagation is collinear under pure mode I loading. In that case, either Irwin’s stress intensity factor theory

Fig. 2 Timeline of mixed-mode fracture criteria. The colors represent a classification accordingly to the supporting argument.

(K_I) or Griffith's energy release theory (G_I) could be used to establish the fracture criterion. But, under general mixed-mode conditions, the stress field at the crack tip is much more complicated to study, due to the interaction of loadings; the crack will no longer grow in its original direction and pertinent fracture criteria are needed to predict mixed mode crack extension.

Even though the earliest fracture criteria were established before 1924, it was not until the mid-60s that appeared a report on mixed-mode loading. [Erdogan and Sih \(1963\)](#) were the first to study the crack extension of brittle material under mixed-mode I/II loading and developed the maximum-stress theory, that states that a crack emerges perpendicularly to the maximum tangential stress at the crack-tip. [Williams and Ewing \(1972\)](#) produced an improved correlation for the angle of fracture by the inclusion of a non-regular term for the stress distribution around the crack tip. [Smith *et al.* \(2001\)](#) described a generalized maximum tensile stress (MTS) criterion with which a more rigorous prediction of the crack initiation angle was obtained. A decade later, at mid-70s, [Sih \(1974\)](#) proposed the minimum-strain energy density criterion or S-criterion, which states that direction of crack threshold coincides with the direction having minimum strain energy density and the crack will grow when the strain energy density reaches a critical value (S_{cr}). As with the maximum-stress theory, various researchers proposed different criteria based on the S-criterion. By the same time, [Hussain *et al.* \(1974\)](#), introduced the G-criterion based on the Griffith energy principle, assuming that, under mixed-mode loading, the crack will grow along its own original plane and that the crack initiation happens at the direction of the maximum of the energy release rate. Since then, many fracture criteria in mixed-mode loading have been published. In general, most of the reported criteria could be classified in four categories: stress-based, energy-based, strain-based and empirical. In [Fig. 2](#) some of the mixed-mode fracture criteria found in the literature are summarized and grouped within this classification.

It is not appropriate to say that one criterion is definitely superior to another. Analysts are still perplexed with selecting an appropriate fracture criterion because it requires much discernment and judgment. Criteria which often appeared valid for idealized situations are quickly discredited in practice in the face of more complex physical phenomena. Furthermore, the assertion of generality should not be on an agreement between theory and experiment for a few simple examples. Due to the lack of globally accepted fracture criteria, the determination of the structure damage, due to material failure, is still under intensive research. From a practical viewpoint, the need for a fracture criterion that can treat real situations is apparent.

Almost all of the proposed mixed-mode fracture criteria were based on linear elastic fracture mechanics (LEFM) and most only involve a combination of mode I/II loading conditions. LEFM assumes a negligible amount of plastic deformation around the crack tip, so that elastic stresses and strains can be used to determine the mechanical behavior of the specimen. According to [Williams \(1956\)](#), in the Cartesian coordinate system (See [Fig. 3\(a\)](#)) the elastic stress field around the crack tip may be expressed as a set of infinite series expansions presented in [Eq. \(1\)](#):

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \tau_{xy} \end{Bmatrix} = \frac{1}{\sqrt{2\pi r}} \begin{bmatrix} \cos \frac{\theta}{2} - \frac{1}{2} \sin \theta \sin \frac{3\theta}{2} & -2 \sin \frac{\theta}{2} + \frac{1}{2} \sin \theta \cos \frac{3\theta}{2} \\ \cos \frac{\theta}{2} + \frac{1}{2} \sin \theta \sin \frac{3\theta}{2} & \frac{1}{2} \sin \theta \cos \frac{3\theta}{2} \\ \frac{1}{2} \sin \theta \cos \frac{3\theta}{2} & \left(\cos \frac{\theta}{2} - \frac{1}{2} \sin \theta \sin \frac{3\theta}{2} \right) \end{bmatrix} \times \begin{Bmatrix} K_I \\ K_{II} \end{Bmatrix} + \begin{bmatrix} T \\ 0 \\ 0 \end{bmatrix} + \begin{Bmatrix} O(r^{1/2}) \\ O(r^{1/2}) \\ O(r^{1/2}) \end{Bmatrix} \quad (1)$$

Fig. 3 Elastic stresses around the crack tip in the: (a) Cartesian coordinate system, and; (b) Polar coordinate system.

where r and θ are the conventional crack tip coordinates and σ_{xx} , σ_{yy} , and τ_{xy} represent the stresses. The first term of the right side of Eq. (1) is singular and depends on the mode I and mode II stress intensity factors (SIFs) K_I and K_{II} . The other two terms of the right side of Eq. (1) are non-singular. The first non-singular term, called “ T -stress”, enters only in σ_{xx} , the parallel-to-the-crack component of stress, and is independent of the distance from the crack tip. The higher order terms in the series expansion $O(r^{1/2})$ are often considered to be negligible near the crack tip. In the polar coordinate system (See Fig. 3(b)), the Williams’ series expansions can be written as:

$$\sigma_{\theta\theta} = \frac{1}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \left[K_I \cos^2 \frac{\theta}{2} - \frac{3}{2} K_{II} \sin \theta \right] + T \sin^2 \theta + O(r^{1/2}) \quad (2)$$

$$\sigma_{rr} = \frac{1}{\sqrt{2\pi r}} \cos \frac{\theta}{2} \left[K_I \left(1 + \sin^2 \frac{\theta}{2} \right) + K_{II} \left(\frac{3}{2} \sin \theta - 2 \tan \frac{\theta}{2} \right) \right] + T \cos^2 \theta + O(r^{1/2}) \quad (3)$$

$$\tau_{r\theta} = \frac{1}{2\sqrt{2\pi r}} \cos \frac{\theta}{2} [K_I \sin \theta + K_{II} (3 \cos \theta - 1)] - T \sin \theta \cos \theta + O(r^{1/2}) \quad (4)$$

where $\sigma_{\theta\theta}$, σ_{rr} and $\tau_{r\theta}$ are the polar stresses. The crack tip parameters K_I , K_{II} , and T are known functions of the external loads and depend on the geometry and loading configurations, as such, then can vary considerably for different specimens. Analytical, experimental and numerical methods are three major techniques for calculating the crack tip parameters (Anderson, 2017). According to Ayatollahi and Aliha (2007), for complicated geometry and loading conditions, the finite element technique has proved to be an useful and comprehensive tool for determining the crack tip parameters.

Maximum Tangential Stress Criterion

Erdogan and Sih (1963) stated two hypotheses for the extension of cracks in a brittle material under slowly applied plane loads: (1) crack extension starts at its tip in radial direction, and; (2) crack extension starts in the plane perpendicular to the direction of greatest tension. These hypotheses imply that the crack will start to grow from the tip in the direction along which the tangential stress $\sigma_{\theta\theta}$, is maximum and the shear stress $\tau_{r\theta}$, is zero. Subsequently, the maximum tangential stress (MTS) criterion suggests that, for a brittle material, crack propagation initiates along the direction θ_0 of maximum tangential stress around the crack tip (See Fig. 4). It is important to note that when the stress intensity at pre-existing crack tip increases to a certain level, the crack (with a half-length, a) (See Fig. 4) will extend a small length, $\bar{a}$, to form a branch crack along the direction θ_0 . In case of initiation of fracture, instead of fracture propagation, the length of $\bar{a}$ can be assumed to shrink to zero. It indicates that the stresses around the tip of branch crack are approximately equal to the stresses (such as $\sigma_{\theta\theta}$ and $\tau_{r\theta}$) at the tip of original crack with a direction $\theta = \theta_0$. Therefore, the angle θ_0 can be found by solving Eq. (5):

$$\frac{\partial \sigma_{\theta\theta}}{\partial \theta} = 0 \Rightarrow \theta = \theta_0 \quad (5)$$

Erdogan and Sih’s MTS criterion (Erdogan and Sih, 1963) ignores the contribution of the non-singular stress term, T -stress, and the higher order terms $O(r^{1/2})$ of the Williams’ model (Eqs. (1)–(4)). Hence, from Eqs. (2) and (5), θ_0 is determined by solving Eq. (6):

$$K_I \sin \theta_0 + K_{II} (3 \cos \theta_0 - 1) = 0 \quad (6)$$

Plugging the value of θ_0 in Eq. (2), the conditions for the onset of crack propagation can be found, as in Eq. (7):

$$\cos \frac{\theta_0}{2} \left[K_I \cos^2 \frac{\theta_0}{2} - \frac{3}{2} K_{II} \sin \theta_0 \right] = \text{constant} = \sqrt{2\pi r_c} (\sigma_{\theta\theta})_c \quad (7)$$

where r_c is the critical radius from the crack tip and $(\sigma_{\theta\theta})_c$ is the critical value of the tangential stress at the critical radius r_c , material properties that are assumed to be independent of the geometry of specimen and loading configuration. Eqs. (6) and (7) describe

Fig. 4 Geometry for the branch crack.

the MTS criterion where mixed mode I/II fracture is predicted for any geometry in which K_I and K_{II} are known. For pure mode I (K_{II} and θ_0 are equal to zero), K_I at fracture can be replaced by the mode I fracture toughness K_{Ic} , that is also a material property, and Eq. (7) reduces to:

$$\sqrt{2\pi r_c}(\sigma_{\theta\theta})_c = K_{Ic} \quad (8)$$

As mentioned earlier, in mixed mode I/II conditions, the crack growth is not in the same plane as the initial crack. For this case, the T -stress contributes to the tangential stress (along the direction of initiation of crack growth) and hence influences the apparent mixed mode fracture toughness. Smith *et al.* (2001) re-examined the role of the T -stress in brittle fracture for linear elastic materials and proposed the generalized MTS criterion (GMTS). GMTS takes into account the effects of both, the singular terms and the T -stress term, in the tangential stress around the crack tip. Retaining both the singular terms and the T -stress in Eqs. (2)–(4), the MTS criterion, θ_0 is determined by solving Eq. (9):

$$[K_I \sin \theta_0 + K_{II}(3 \cos \theta_0 - 1)] - \gamma \sin \frac{\theta_0}{2} \cos \theta_0 = 0 \quad (9)$$

where:

$$\gamma = 16(T\sqrt{2\pi r_c})/3 = 16(B\alpha K_{eff})/3 \quad (10)$$

$$B = (T\sqrt{\pi a})/K_{eff} \quad (11)$$

$$\alpha = \sqrt{2r_c/a} \quad (12)$$

$$K_{eff} = \sqrt{(K_I^2 + K_{II}^2)} \quad (13)$$

B is often called the biaxiality ratio, since it is equal to the ratio of T -stress to the effective stress intensity factor (K_{eff}), α is the dimensionless form of the critical radius from the crack tip, a is the crack length (semi-crack length for center cracks and the crack length for edge-cracks). Therefore, the conditions for the onset of crack propagation are giving by:

$$\cos \frac{\theta_0}{2} \left[K_I \cos^2 \frac{\theta_0}{2} - \frac{3}{2} K_{II} \sin \theta_0 \right] = K_{Ic} - T\sqrt{2\pi r_c} \sin^2 \theta_0 \quad (14)$$

or, in term of the biaxiality ratio, B :

$$\cos \frac{\theta_0}{2} \left[K_I \cos^2 \frac{\theta_0}{2} - \frac{3}{2} K_{II} \sin \theta_0 \right] = -B\alpha K_{eff} \sin^2 \theta_0 + K_{Ic} \quad (15)$$

Using this criterion, the direction and the onset of fracture initiation can be predicted for any combination of the crack tip parameters K_I , K_{II} and T . Smith *et al.* (2001) also defined the mixity parameter M^e given in Eq. (16):

$$M^e = \frac{2}{\pi} \tan^{-1} \left(\frac{K_I}{K_{II}} \right) \quad (16)$$

The value of M^e is one for pure mode I and zero for pure mode II. Usually, it is shown that positive T reduces the apparent fracture toughness in mixed mode loading and a negative T increases it (Smith *et al.*, 2001). In 2014, Akbardoost and Ayatollahi (2014) proposed a modified form of MTS (MMTS) criterion which takes into account the effects of three non-singular stress terms (T , A_3 and B_3) in addition to the singular terms (SIFs). A_3 and B_3 are constant coefficients of the third terms in the Williams series expansion for the tangential stress component, $\sigma_{\theta\theta}$, around the crack tip that now can be written as:

Fig. 5 Location of the maximum surface tangential strain, point M, and its stress element.

$$\begin{aligned} \sigma_{\theta\theta} = & \frac{3}{4} \frac{K_I}{\sqrt{2\pi r}} \left(\cos \frac{\theta}{2} + \frac{1}{3} \cos \frac{3\theta}{2} \right) + T \sin^2 \theta + \frac{15}{4} \sqrt{r} A_3 \left(\cos \frac{\theta}{2} - \frac{1}{5} \cos \frac{5\theta}{2} \right) - \frac{3}{4} \frac{K_{II}}{\sqrt{2\pi r}} \left(\sin \frac{\theta}{2} + \sin \frac{3\theta}{2} \right) \\ & - \frac{15}{4} \sqrt{r} B_3 \left(\sin \frac{\theta}{2} - \sin \frac{5\theta}{2} \right) + O(r) \end{aligned} \quad (17)$$

The fracture parameters K_I , K_{II} , T , A_3 and B_3 are known and depend on the geometry and loading conditions of the test specimen and their magnitudes may vary over a wide range for different test samples. The MMTS criterion ignores the remaining terms of the series expansion represented by $O(r)$. Similar to MTS and GMTS criterion, using Eqs. (2) and (17), an expression for θ_0 can be obtained in order to predict the mixed mode I/II fracture resistance. The predicted curves using MMTS criterion, based on a more accurate equation in which higher order terms of Williams expansion are taken into account, show better agreement with reported experimental results than other conventional criteria.

Maximum Tangential Strain Criterion

Chang (1981) modified the maximum-normal-strain theory of St-Venant and applied it to the study of the angled crack problem. This modified criterion, called maximum tangential strain (MTSN) criterion, states: (1) Crack extension starts from the location of the maximum surface tangential strain (point M in Fig. 5), along a direction θ equal to θ_0 , at which the circumferential strain $\varepsilon_{\theta\theta}$, on a circular arc of (small) radius r_c from point M, reaches a maximum value with respect to θ , and; (b) Fracture is imminent when the maximum strain $\varepsilon_{\theta\theta}$, at the distance r_c from point M, reaches a critical value ε_F . These statements are equivalent to Eqs. (18)–(19) below.

$$\left. \frac{\partial \varepsilon_{\theta\theta}}{\partial \theta} \right|_{r=r_c; \theta=\theta_0} = 0 \quad (18)$$

$$\left. \frac{\partial^2 \varepsilon_{\theta\theta}}{\partial \theta^2} \right|_{r=r_c; \theta=\theta_0} < 0 \quad (19)$$

$$(\varepsilon_{\theta\theta})_c = \varepsilon_F = \sigma_F / E \quad (20)$$

where σ_F is the tensile fracture strength and E is Young's modulus of the material. The critical distance r_c could be considered as damaged zone around the crack tip which is a material property. The linear elastic relationship between the tangential strain and stress components is given by Eq. (21):

$$\varepsilon_{\theta\theta} = \frac{1}{E} (\sigma_{\theta\theta} - \nu \sigma_{rr}) \quad (21)$$

where ν is the Poisson's ratio and $\sigma_{\theta\theta}$ and σ_{rr} are the tangential and radial components of the stress field polar coordinate system, respectively. The MTSN criterion claims that fracture initiation depends not only on the geometry and boundary conditions but also on the Poisson's ratio, ν , of the material. It is clear from Eq. (21) that predictions based on MTSN criterion will coincide with those made with MTS criterion when $\nu = 0$. Substituting Eqs. (2) and (3) into Eq. (21), and taking into account only the singular stress terms (associated with the K_I and K_{II}), the conventional MTSN could be represented by Eqs. (22) and (23):

$$\frac{K_I}{E\sqrt{2\pi r_c}} \{f'_{\theta\theta,1}(\theta_0) - \nu \times f'_{rr,1}(\theta_0)\} + \frac{K_{II}}{E\sqrt{2\pi r_c}} \{f'_{\theta\theta,2}(\theta_0) - \nu \times f'_{rr,2}(\theta_0)\} = 0 \quad (22)$$

$$\frac{K_I}{E\sqrt{2\pi r_c}} \{f_{\theta\theta,1}(\theta_0) - \nu \times f_{rr,1}(\theta_0)\} + \frac{K_{II}}{E\sqrt{2\pi r_c}} \{f_{\theta\theta,2}(\theta_0) - \nu \times f_{rr,2}(\theta_0)\} = \varepsilon_F = \sigma_F/E \quad (23)$$

where

$$f'_{ij,n}(\theta_0) = \frac{\partial}{\partial \theta} [f_{ij,n}(\theta)] \Big|_{\theta=\theta_0} \quad (24)$$

and $(i, j) \equiv (r, \theta)$ are the polar coordinates with the origin at the crack tip and the functions $f_{ij,n}(\theta)$ [$ij \equiv r, \theta; n \equiv 1$ (mode I, opening), 2 (mode II, sliding)] are given by Eqs. (25)–(28):

$$f_{rr,1}(\theta) = \frac{1}{4} \left(5\cos\frac{\theta}{2} - \cos\frac{3\theta}{2} \right) \quad (25)$$

$$f_{rr,2}(\theta) = \frac{1}{4} \left(-5\sin\frac{\theta}{2} + 6\sin\frac{3\theta}{2} \right) \quad (26)$$

$$f_{\theta\theta,1}(\theta) = \frac{1}{4} \left(3\cos\frac{\theta}{2} + \cos\frac{3\theta}{2} \right) \quad (27)$$

$$f_{\theta\theta,2}(\theta) = \frac{1}{4} \left(-3\sin\frac{\theta}{2} - \sin\frac{3\theta}{2} \right) \quad (28)$$

Fracture initiation angle, θ_0 , obtained from Eq. (22), is used to find the onset conditions of fracture when the left-hand side of the Eq. (23) reaches the tensile fracture strength. Mirsayar (2015) modified the MTSN criterion and proposed the extended version of the maximum tangential strain (EMTSN), retaining singular stress terms and adding the T -stress into Eq. (21). Hence, Eqs. (22) and (23) can be written as:

$$\frac{K_I}{E\sqrt{2\pi r_c}} \{f'_{\theta\theta,1}(\theta_0) - \nu \times f'_{rr,1}(\theta_0)\} + \frac{K_{II}}{E\sqrt{2\pi r_c}} \{f'_{\theta\theta,2}(\theta_0) - \nu \times f'_{rr,2}(\theta_0)\} + (1 + \nu) \frac{T}{E} \sin(2\theta_0) = 0 \quad (29)$$

$$\frac{K_I}{E\sqrt{2\pi r_c}} \{f_{\theta\theta,1}(\theta_0) - \nu \times f_{rr,1}(\theta_0)\} + \frac{K_{II}}{E\sqrt{2\pi r_c}} \{f_{\theta\theta,2}(\theta_0) - \nu \times f_{rr,2}(\theta_0)\} + \frac{T}{E} [\sin^2(\theta_0) - \nu \cos^2(\theta_0)] = \sigma_F/E \quad (30)$$

or, in term of biaxiality ratio, B (Eq. (11)):

$$K_I \{f_{\theta\theta,1}(\theta_0) - \nu \times f_{rr,1}(\theta_0)\} + K_{II} \{f_{\theta\theta,2}(\theta_0) - \nu \times f_{rr,2}(\theta_0)\} = \sigma_F \sqrt{2\pi r_c} - B\alpha K_{eff} [\sin^2(\theta_0) - \nu \cos^2(\theta_0)] \quad (31)$$

In Eq. (30), the first non-singular tangential strain term in the left hand of the equation, corresponding to parameter T , is called “tangential T -strain”. This tangential T -strain is equal to the well-known T -stress, defined by Williams (1956). Radial and shear components are associated within the tangential T -strain term and, normally, they are determined by finite element analysis. Finally, Mirsayar (2015) defined the parameter K_{Ic}^* , identified as “generalized fracture toughness”, as in Eq. (32), that takes into account the effect of both Poisson’s ratio and specimen geometry ($B\alpha$) in calculation of the mode I fracture toughness.

$$K_{Ic}^* = \frac{\sigma_F \sqrt{2\pi r_c}}{1 - \nu(1 + B\alpha)} \quad (32)$$

Energy-Based Criteria

Maximum energy release rate criterion

Hussain *et al.* (1974) proposed the maximum energy release rate (MERR) criterion, for which the fracture takes place from the crack tip along the direction (θ_0) of maximum energy release rate. Departing from Griffith’s energy release theory, they computed the energy release rate G for combined mode I and mode II under plane stress conditions as:

$$G = \frac{1}{E} (K_I^2 + K_{II}^2) \quad (33)$$

where K_I and K_{II} are the SIFs for mode I and mode II, respectively; and E is the Young’s modulus of the material. Eq. (33) was obtained by assuming that the crack, under combined loading, moves along its own initial plane. Unfortunately, the crack extension is not collinear, for a crack subjected to either skew-symmetric loads or combined loads. Hence, an equation that would give the energy release rate for an arbitrary direction of crack propagation is necessary for applying the Griffith-Irwin energy release rate criterion to cracks under combined loads. When the fracture initiation takes place running apart from the original crack, in the direction $\theta = \theta_0$, the energy release rate for the branch crack, G_θ , can be obtained from Eq. (34):

$$G_\theta = \frac{2\pi r}{E'} (\sigma_{\theta\theta}^2 + \tau_{r\theta}^2) \quad (34)$$

where E' equals E for plane stress condition, or $[E/(1 - \nu^2)]$ for plane strain condition, with E and ν the Young’s modulus and Poisson’s ratio, respectively. According to MERR criterion when the energy release rate along the direction θ_0 and at a critical distance r_c from the crack tip reaches its critical value, the crack initiation will take place along the fracture initiation angle θ_0 . Therefore, the fracture initiation angle θ_0 can be determined by solving the following equations:

$$\left. \frac{\partial G_\theta}{\partial \theta} \right|_{r=r_c; \theta=\theta_0} = 0 \quad (35)$$

$$\left. \frac{\partial^2 G_\theta}{\partial \theta^2} \right|_{r=r_c; \theta=\theta_0} < 0 \quad (36)$$

If the energy release rate due to the initiation of a branch crack only depends on the stress state before fracture begins, Eqs. (2) and (4) can be used to rewrite Eq. (34) (ignoring the high order term $O(r^{1/2})$), and the energy release rate G_θ can be obtained as:

$$G_\theta = \frac{1}{E'} \left[B_1 K_I^2 + B_2 K_{II}^2 + B_3 K_I K_{II} + B_4 \sqrt{2\pi r} K_I T + B_5 \sqrt{2\pi r} K_{II} T + B_6 (2\pi r) T^2 \right] \quad (37)$$

where

$$B_1 = \frac{1}{4} (\cos \theta + 1)^2 \quad (38)$$

$$B_2 = -3 \sin^4 \frac{\theta}{2} + 2 \sin^2 \frac{\theta}{2} + 1 \quad (39)$$

$$B_3 = -\frac{1}{2} \sin(2\theta) - \sin \theta \quad (40)$$

$$B_4 = -4 \cos^5 \frac{\theta}{2} + 4 \cos^3 \frac{\theta}{2} \quad (41)$$

$$B_5 = 4 \sin^5 \frac{\theta}{2} - 4 \sin^3 \frac{\theta}{2} \quad (42)$$

$$B_6 = \sin^2 \theta \quad (43)$$

Eq. (37) for G_θ into Eq. (35), gives θ_0 as the solution of Eq. (44):

$$C_1 K_I^2 + C_2 K_{II}^2 + C_3 K_I K_{II} + C_4 \sqrt{2\pi r_c} K_I T + C_5 \sqrt{2\pi r_c} K_{II} T + C_6 (2\pi r_c) T^2 = 0 \quad (44)$$

in which

$$C_1 = -\frac{1}{4} \sin(2\theta_0) - \frac{1}{2} \sin \theta_0 \quad (45)$$

$$C_2 = \frac{3}{4} \sin(2\theta_0) - \frac{1}{2} \sin \theta_0 \quad (46)$$

$$C_3 = -2 \cos^2 \theta_0 - \cos \theta_0 + 1 \quad (47)$$

$$C_4 = 10 \sin^5 \frac{\theta_0}{2} - 14 \sin^3 \frac{\theta_0}{2} + 4 \sin \frac{\theta_0}{2} \quad (48)$$

$$C_5 = 10 \cos^5 \frac{\theta_0}{2} - 20 \cos^3 \frac{\theta_0}{2} + 8 \cos \frac{\theta_0}{2} \quad (49)$$

$$C_6 = \sin(2\theta_0) \quad (50)$$

When the energy release rate at the crack tip reaches a critical value, the crack starts to grow. At this time:

$$G_\theta = G_{\theta c} \quad (51)$$

where $G_{\theta c}$ is the critical value of the energy release rate at the critical distance r_c along the direction $\theta = \theta_0$. Combining the Eqs. (37) and (51), the following equation can be obtained:

$$G_{\theta c} = \frac{1}{E'} \left[B_1 K_I^2 + B_2 K_{II}^2 + B_3 K_I K_{II} + B_4 \sqrt{2\pi r_c} K_I T + B_5 \sqrt{2\pi r_c} K_{II} T + B_6 (2\pi r_c) T^2 \right] \quad (52)$$

For pure mode I when K_{II} and θ_0 are equal to zero, K_I at fracture can be replaced by the mode I fracture toughness K_{Ic} , that is a material property, and Eq. (52) reduces to:

$$G_{\theta c} = \frac{1}{E'} K_{Ic}^2 \quad (53)$$

Therefore, Eq. (52) can be rewritten as:

$$K_{Ic}^2 = B_1 K_I^2 + B_2 K_{II}^2 + B_3 K_I K_{II} + B_4 \sqrt{2\pi r_c} K_I T + B_5 \sqrt{2\pi r_c} K_{II} T + B_6 (2\pi r_c) T^2 \quad (54)$$

Eqs. (44) and (54) can be used to predict the initiation of the mixed mode I/II crack and the model is called "generalized maximum energy release rate criterion" (GMERR), proposed by Hou *et al.* (2019) as an improvement of the conventional MERR criterion, in consideration to the important role that T -stress plays in the fracture analysis of the materials under mixed mode loading. It is, also, a way to avoid the overestimating or underestimating of the fracture initiation angles and fracture resistances.

Strain-energy-density criterion

The search for a quantity that would provide a description of the direction of crack growth under mixed mode I/II conditions, as well as a measure of the intrinsic property of the material, led to model the energy concentrated in the crack tip region where fracture may take place. Sih (1974) modeled the strain-energy density distribution around the crack tip by considering that the strain energy stored dW , in the element dA for a plane elasticity problem can be found from:

$$\frac{dW}{dA} = \frac{1}{2\mu} \left[\frac{\kappa+1}{8} (\sigma_{rr} + \sigma_{\theta\theta})^2 - \sigma_{rr}\sigma_{\theta\theta} + \tau_{r\theta}^2 \right] \quad (55)$$

where $\sigma_{\theta\theta}$, σ_{rr} and $\tau_{r\theta}$ are the polar stresses, μ is the modulus of rigidity or shear modulus equal to $[E/2(1+\nu)]$ and κ is an elastic constant that equals $(3-4\nu)$ or $[(3-\nu)/(1+\nu)]$ for the plane strain or for plane stress problems, respectively. Therefore, the strain energy density factor, S , which represents the strength of the elastic energy field in the vicinity of the crack tip can be defined as:

$$S = r \frac{dW}{dA} = \frac{r}{2\mu} \left[\frac{\kappa+1}{8} (\sigma_{rr} + \sigma_{\theta\theta})^2 - \sigma_{rr}\sigma_{\theta\theta} + \tau_{r\theta}^2 \right] \quad (56)$$

Sih (1974) proposed the strain-energy-density (SED) criterion, that consider as hypotheses for crack initiation in a two-dimensional stress field that: (1) The initial crack growth takes place in the direction along $\theta = \theta_0$ which the strain-energy-density factor possesses a stationary (minimum), and; (2) Crack initiation occurs when the strain-energy-density factor reaches a critical value, S_{cr} . This criterion represented by:

$$\left. \frac{\partial S}{\partial \theta} \right|_{r=r_c; \theta=\theta_0} = 0 \quad (57)$$

$$\left. \frac{\partial^2 S}{\partial \theta^2} \right|_{r=r_c; \theta=\theta_0} > 0 \quad (58)$$

$$S = S_{cr} \text{ for } \theta = \theta_0 \text{ and } r = r_c \quad (59)$$

By replacing the stress components from Eqs. (2), (3) and (4) into Eq. (56), the strain energy density factor S , can be written as:

$$S = a_1 K_I^2 + a_2 K_{II}^2 + a_3 K_I K_{II} + a_4 K_I T + a_5 K_{II} T + a_6 T^2 \quad (60)$$

where

$$a_1 = \frac{1}{16\pi\mu} (\kappa - \cos\theta)(1 + \cos\theta) \quad (61)$$

$$a_2 = \frac{1}{16\pi\mu} [\kappa(1 - \cos\theta) + \cos\theta(1 + 3\cos\theta)] \quad (62)$$

$$a_3 = \frac{1}{8\pi\mu} \sin\theta [2\cos\theta - (\kappa - 1)] \quad (63)$$

$$a_4 = \frac{\sqrt{2r}}{8\sqrt{\pi\mu}} \cos\frac{\theta}{2} [\cos(2\theta) - \cos\theta + (\kappa - 1)] \quad (64)$$

$$a_5 = -\frac{\sqrt{2r}}{8\sqrt{\pi\mu}} \sin\frac{\theta}{2} [\cos(2\theta) + \cos\theta + (\kappa + 1)] \quad (65)$$

$$a_6 = \frac{(\kappa + 1)r}{16\mu} \quad (66)$$

Substituting the Eq. (60) into Eq. (57), the angle θ_0 can be found from:

$$c_1 K_I^2 + c_2 K_{II}^2 + c_3 K_I K_{II} + c_4 (B\alpha K_{eff}) K_I + c_5 (B\alpha K_{eff}) K_{II} + c_6 (B\alpha K_{eff})^2 = 0 \quad (67)$$

in which

$$c_1 = \frac{1}{16\pi\mu} \sin\theta_0 (2\cos\theta_0 - \kappa + 1) \quad (68)$$

$$c_2 = -\frac{1}{16\pi\mu} \sin\theta_0 (6\cos\theta_0 - \kappa + 1) \quad (69)$$

$$c_3 = \frac{1}{8\pi\mu} [2\cos(2\theta_0) - (\kappa - 1)\cos\theta_0] \quad (70)$$

$$c_4 = -\frac{1}{16\pi\mu} \sin\frac{\theta_0}{2} \left\{ 5[\cos(2\theta_0) + \cos\theta_0] + (\kappa + 1) \right\} \quad (71)$$

$$c_5 = -\frac{1}{16\pi\mu} \cos\frac{\theta_0}{2} \left\{ 5[\cos(2\theta_0) - \cos\theta_0] + (\kappa + 3) \right\} \quad (72)$$

Fig. 6 Geometry of kinked crack.

$$c_6 = 0 \quad (73)$$

As before, B is the biaxiality ratio of Eq. (11), α is the dimensionless form of the critical radius from the crack tip and K_{eff} is the effective stress intensity factor. By substituting the angle of crack growth (θ_0) into Eq. (60), the onset of crack propagation can be determined. Brittle fracture takes place when the SED factor reaches its critical value S_{cr} . According to Sih (1974), there is a direct relation between S_{cr} and mode I fracture toughness K_{Ic} as:

$$S_{cr} = \frac{1}{8\pi\mu} (\kappa - 1) K_{Ic}^2 \quad (74)$$

Conventional SED criterion only considers the singular terms of Williams' expansion. Ayatollahi *et al.* (2015) introduced the effect of T-stress in addition to the stress intensity factors K_I and K_{II} that are already present in the conventional SED criterion and developed the model called the generalized strain energy density (GSED) criterion, as described in the Eqs. (60) and (67). The advantage of the generalized SED criterion relative to the conventional SED criterion is more noticeable in cracked components that have significant value of T-stress under mixed mode loading and for materials that possess large critical distances.

Other criterion based on strain-density-energy were proposed by Lazzarin and Zambardi (2001) and Moghaddam *et al.* (2017). In Lazzarin and Zambardi (2001), the averaged strain energy density (ASED) criterion in order to predict the mixed mode I/II fracture resistance of brittle and quasi-brittle materials is proposed. This criterion utilizes the deformation energy averaged in a control volume of radius r_c to estimate the fracture load for both cracked and notched specimens. In crack problems, the control volume has a circular shape and its radius r_c is a material property. Brittle fracture takes place when the averaged value of the deformation energy inside the control volume reaches a critical value (also a material property). To obtain the average value of strain energy density around the crack tip finite element analysis is used. In Moghaddam *et al.* (2017) a modified energy-based model called the generalized averaged strain energy density (GASED) criterion is proposed. It considers the effect of T-stress in addition to the stress intensity factors K_I and K_{II} in the Williams' series expansion when calculating the strain energy density averaged in a control volume around the crack tip.

Empirical Criterion

The three criteria reviewed in the sections above, although different in their approaches, result in very similar predictions for both the directions of crack extensions and the critical conditions of loading for mixed mode fracture. These theoretical predictions can also be fitted very closely with the empirical function of the equation proposed by Palaniswamy and Knauss (1978):

$$\left(\frac{K_I}{K_{Ic}}\right) + \frac{3}{2} \left(\frac{K_{II}}{K_{Ic}}\right)^2 = 1 \quad (75)$$

where K_I and K_{II} are the mode I and mode II SIFs; and K_{Ic} is the mode I fracture toughness. Under mixed mode I/II loading, Cotterell and Rice (1980) suggested that a crack may extend in a plane deviating from the original by kinking. Such a kink of length, l , with a sudden change of the original direction by an angle, β , is shown in Fig. 6.

According to Bilby *et al.* (1978) and Cotterell and Rice (1980), the local mixed-mode stress intensity factors k_I and k_{II} can be computed from the singular stress field produced ahead of the original (unkinked) crack as:

$$K_I = c_{11}K_I + c_{12}K_{II} \quad (76)$$

$$K_{II} = c_{21}K_I + c_{22}K_{II} \quad (77)$$

where

$$C_{11} = \cos^3\left(\frac{\beta}{2}\right) \quad (78)$$

$$C_{12} = -3\sin\left(\frac{\beta}{2}\right)\cos^2\left(\frac{\beta}{2}\right) - \frac{1}{3}\sin^3\left(\frac{\beta}{2}\right) \quad (79)$$

$$C_{21} = \sin\left(\frac{\beta}{2}\right) \cos^2\left(\frac{\beta}{2}\right) \quad (80)$$

$$C_{22} = \cos\left(\frac{\beta}{2}\right) \left[1 - 3\sin^2\left(\frac{\beta}{2}\right)\right] + \frac{1}{6}\sin^2\left(\frac{4\beta}{5}\right) \quad (81)$$

For the limit case $K_{II} \ll K_I$ ($K_{II}/K_I \rightarrow 0$), expansion of Eqs. (78) and (79) can be obtained and an approximation of k_I can be found from:

$$K_I = \left(1 - \frac{3}{8}\beta^2\right)K_I - \left(\frac{3}{2}\beta\right)K_{II} \quad (82)$$

The maximum value of k_I results from solving:

$$\frac{dk_I}{d\beta} = 0 \quad (83)$$

and thus,

$$\beta = -2\frac{K_{II}}{K_I} \quad (84)$$

Substituting Eq. (84) into Eq. (82) and assuming the failure will occur if k_I reaches the value K_{Ic} ($k_I = K_{Ic}$), Eq. (85) can be obtained:

$$K_I^2 - K_{Ic}K_I + \frac{3}{2}K_{II}^2 = 0 \quad (85)$$

Solving the quadratic equation and simplifying:

$$K_I = \frac{1}{2}K_{Ic} \left[1 \pm \sqrt{1 - 6\left(\frac{K_{II}}{K_{Ic}}\right)^2}\right] \cong \frac{1}{2}K_{Ic} \left\{1 \pm \left[1 - 3\left(\frac{K_{II}}{K_{Ic}}\right)^2\right]\right\} \rightarrow \left(\frac{K_I}{K_{Ic}}\right) + \frac{3}{2}\left(\frac{K_{II}}{K_{Ic}}\right)^2 = 1; \text{ with } \beta = -2\frac{K_{II}}{K_I} \quad (86)$$

and, thus, the empirical criterion, proposed by Palaniswamy and Knauss (1978), is finally obtained. For the limit case $K_{II} \gg K_I$ ($K_{II}/K_I \rightarrow \infty$), it is necessary to deduce the maximum value of the function C_{12} :

$$\max[C_{12}] = C_{12}(\beta_{\max}) = 1.2247 \quad (87)$$

therefore

$$\beta_{\max} \cong -1.33(-76^\circ) \quad (88)$$

The value of the crack deflection angle under pure mode II loading obtained by this empirical criterion ($\beta_{\max} = -76^\circ$) is close to the values calculated using MTS criterion ($\theta_0 = -70.5^\circ$) (Erdogan and Sih, 1963) and SED criterion ($\theta_0 = -79.2^\circ$, with $\nu = 0.22$) (Sih, 1974). Richard (1985) proposed an empirical criterion with the form:

$$\left(\frac{K_I}{K_{Ic}}\right)^u + \left(\alpha\frac{K_{II}}{K_{Ic}}\right)^v = 1 \quad (89)$$

where u and v are exponents that could be varied in order to obtain a reasonably good fit to the experimental data and α is the relation between mode I fracture toughness K_{Ic} and mode II fracture toughness K_{IIc} ($\alpha = K_{Ic}/K_{IIc}$). When $u = 1$, $v = 2$ and $\alpha = \sqrt{3}/2 = 1.2247$, the Richard's criterion is exactly the empirical criterion proposed by Palaniswamy and Knauss (1978) (Eq. 75), and the value of the coefficient α is in agreement with the limit case $K_{II} \gg K_I$, as can be seen from Eq. (86).

Testing in Mixed-Mode Fracture

It is widely recognized that catastrophic fracture can be initiated in structural ceramic components at cracks or preexisting flaws which are oriented at arbitrary angles to the far-field loading directions or subjected to multiaxial stresses. According to Suresh *et al.* (1990), the efficient and safe design of advanced ceramics for potential structural applications inevitably requires the development of fracture data and failure criteria for combinations of mode I (tensile opening), mode II (in-plane shear), or mode III (tearing) loading. Several studies had been conducted on mixed-mode fracture of ceramic materials, but, unfortunately, conflicting experimental results have generated controversy and discussions on the validity of multiaxial test data and failure criteria.

This begins with a suitable fracture test specimen, that should have some benefits such as simple configuration, inexpensive preparation method, ease of loading set-up and ability of providing full loading conditions ranging from pure mode I to pure mode II (Pirmohammad and Mengharpey, 2018). For the determination of combined mode I/II fracture initiation resistance in ceramics, researchers have been employed various fracture test specimens for conducting mixed mode I/II experiments, among them it is worth to mention: inclined Knoop surface flaw in bending bars (Petrovic *et al.*, 1975; Petrovic and Mendiratta, 1976; Munz and Fett, 1999), Oblique Edge Notched Beam (OENB) (Fett *et al.*, 1995), Single Edge Notched Beam (SENB) (Fett *et al.*, 1995; Xeidakis *et al.*, 1996; Paulino and Kim, 2004), Brazilian Disc specimen (BD) (Shetty *et al.*, 1983, 1986, 1987; Shetty, 1987; Atahan *et al.*, 2005), Compact Shear specimen (CS) (Hoyniak and Conway, 1979; Marsavina *et al.*, 2017), Single Edge Crack (SEC)

Table 1 Resume of fracture test specimens for conducting mixed mode I/II experiments and loading conditions

Fracture test specimen	Geometry	Observations
Inclined Knoop surface flaw	 Thickness: t	– A single Knoop surface flaw, with a depth a and a surface length $2c$, is placed on the tensile surface at an orientation angle θ with respect to the specimen length axis. The externally applied uniaxial stress σ^* (performed with a 4-point bending test) gives rise to a stress normal to the crack and a shear stress τ in the crack plane: $\sigma_{n(x)} = \sigma^*_{(x)} \sin^2 \theta \quad (90)$ $\tau_{(x)} = \sigma^*_{(x)} \sin \theta \cos \theta \quad (91)$

In a bending test σ^* decreases linearly with the distance from the surface. The Knoop crack was assumed to be a semi-circular crack, which is nearly in agreement with experimental results, and the decrease of σ^* was neglected ($a/t \ll 1$). The stress intensity factors used were for a crack in an infinite body where surface effects are ignored:

$$K_I = \left(2\sqrt{a/\pi} \right) \sigma_n \quad (92)$$

$$K_{II} = \left(\frac{4}{2-v} \sqrt{a/\pi} \right) \tau \sin \beta \quad (93)$$

$$K_{III} = \left[\frac{4(1-v)}{2-v} \sqrt{a/\pi} \right] \tau \cos \beta \quad (94)$$

(Petrovic *et al.*, 1975; Petrovic and Mendiratta, 1976; Munz and Fett, 1999)

At the depth of the flaw ($\beta = 0^\circ$), only modes I and III are present, giving the stress intensity factors K_I and K_{III} with $K_{II} = 0$. The value of K_{III} is maximum at this site. At the surface of the flaw ($\beta = 90^\circ$), only modes I and II operate, leading to the stress intensity factors K_I and K_{II} with $K_{III} = 0$. The value of K_{II} is maximum at this site. For intermediate locations along the flaw periphery, all 3 displacement modes are present.

OENB (Oblique Edge Notched Beam)

– The oblique edge-crack plate in four-point bending can be used for the determination of fracture toughness under mixed-mode condition. The stress intensity factors, K_I and K_{II} , are given by

$$K_I = \sigma Y_I \sqrt{\pi a} \quad (95)$$

$$K_{II} = \sigma Y_{II} \sqrt{\pi a} \quad (96)$$

$$\sigma = \frac{3S_1 - S_2}{2tW^2} F \quad (97)$$

where t is the specimen thickness and Y_I , Y_{II} are geometric functions based on the influence of the crack length a/W and the angle β .

(Continued)

(Fett *et al.*, 1995)

Table 1 Continued

Fracture test specimen	Geometry	Observations
SENB (Single Edge Notched Beam)	– Three-point bending configuration for pure mode I ($L_3=L_4$; $K_{II}/K_I = 0$)  Thickness: t – Asymmetric four-point bending (AFPB) configuration for pure mode II ($L_1=L_4 < L_2=L_3$; $K_{II}/K_I \rightarrow \infty$)  Thickness: t	– Simple and effective method. Easy to introduce the notch. – Different bending configurations (three-point bending and asymmetric four-point bending) are necessary to change the mode of fracture from pure mode I (tensile) to pure mode II (shear). – The stress analysis of the beam (determination of K_I and K_{II}) is usually determined by a suitable finite element computer program.
(Fett <i>et al.</i> , 1995; Xeidakis <i>et al.</i> , 1996; Paulino and Kim, 2004)	– Three-point bending configuration for mixed mode loading ($L_1 \neq L_3 \neq L_4$). For example, if $L_4 = \frac{1}{4}L_3 = \frac{1}{3}L_1$; $K_{II}/K_I = 0.33$.  Thickness: t	
BD (Brazilian Disc)	 Thickness: t	– A centrally cracked disc is subjected to diametral compression. By changing the inclination of the notch with respect to the loading direction (α), it is possible to change the mode of fracture from pure mode I (tensile) to pure mode II (shear). – The resulting through-cracks can be analyzed precisely for K_I and K_{II} by available solutions. Better predictions can be obtained including the second order non-singular terms in the expressions for the crack-tip stresses (T-stress). Likewise, a finite element analysis can be used to determine SIFs and T-stress values.
CS (Compact Shear)		– Use in the determination of pure mode II fracture toughness. K_{II} is usually determined by a finite element analysis.

(Continued)

Table 1 Continued

Fracture test specimen	Geometry	Observations
SEC (Single Edge Crack)	 Thickness: t	– The single edge crack (SEC) specimen with Arcan grips can produce from pure mode I to pure mode II only by changing the loading angle, β. The loading angle are $\beta = 0^\circ$ and $\beta = 90^\circ$ for mode I test and mode II test, respectively. Mixed mode loading conditions can be obtained with $0^\circ \leq \beta \leq 90^\circ$. Stress intensity factors solutions can be achieved by finite element analysis.
SCB (semi-circular bend specimen)	 Thickness: t	– The SCB specimen is a semi-circle of radius R containing an edge crack of length, a. The crack makes an angle β relative to the vertical direction. The specimen is placed on two bottom supports of distance $2S$ and is loaded by the vertical load F. When the specimen is subjected to three-point bending, depending on $(a/R, S/R, \beta)$ various combinations of modes I and II are obtained. When $\beta = 0^\circ$ the specimen is subjected to pure mode I (opening mode) independent of a/R and S/R. By increasing the angle β, the mode II (or sliding mode) contribution in the crack deformation is increased. Pure mode II takes place in a specific angle β depending on a/R and S/R. SIFs and T-stress can be calculated using a finite element method.
ASCB (asymmetric semicircular bend specimen)	 Thickness: t	– The asymmetric semi-circular bend (ASCB) specimen is used to perform mode I, mode II and mixed mode fracture toughness tests. This semi-circular specimen with radius R, which contains an edge crack of length a oriented normal to the specimen edge, loaded with a three-point bend fixture, was proved to give a wide range of mixed modes from pure mode I ($S_1 = S_2$) to pure mode II ($S_1 \neq S_2$). SIFs and T-stress can be calculated using a finite element method.

(Marsavina *et al.*, 2015, 2017), Semi-Circular Bend specimen (SCB) (Ayatollahi *et al.*, 2006) and Asymmetric Semi-Circular Bend specimen (ASCB) (Ayatollahi *et al.*, 2011; Negru *et al.*, 2013; Marsavina *et al.*, 2015). **Table 1** summarizes the schematic of some testing configurations for mixed-mode loading evaluations, as well as some comments about them.

A significant source of uncertainty in the experimental measurement of intrinsic mixed-mode fracture toughness in ceramics, is the experimental problem of introducing a “sharp” pre-crack prior to the mixed-mode fracture test. In most experimental studies,

the Knoop microhardness indentation technique is used to produce small, controlled surface flaws. This simple technique has the advantage that indented flaws could be taken as strength-limiting defects in structural ceramics. However, it is evident that the generation of residual stresses, due to plastic deformation at the root of the indentation, can markedly influence subsequent fracture. Other source of uncertainty arises from the possibility of frictional sliding between the faces of the crack, especially in coarse-grained microstructures and materials which exhibit pronounced resistance curves (Suresh *et al.*, 1990; Tikare and Choi, 1993). It is then expected that the length of the pre-crack, introduced in the test specimen prior to the mixed-mode experiment, can have a decisive effect on the measured toughness. Therefore, information about mixed-mode fracture initiation toughness, gathered from laboratory test specimens containing long pre-cracks, may lead to dangerously non-conservative guidelines for design against multiaxial fracture in structural ceramic components containing small internal flaws (Anderson, 2017).

Microstructural Effects During Mixed-Mode Fracture

The understanding of the mechanical behavior of ceramics has improved considerably as a direct result of the application of fracture mechanics to ceramics. These concepts have been applied successfully to glasses, mainly because the microstructure is usually defect-free and almost featureless down to the atomic scale and the fracture process can be modeled in an isotropic continuum. In contrast, polycrystalline ceramic materials are not microstructurally homogeneous and the variations in properties as a consequence of fabrication technique, defect distributions and anisotropy have to be taken into account. Different microstructural parameters present in polycrystalline materials like grain and pore size distribution, grain and pore morphology, grain-boundary interactions and phase distribution become significant on the crack propagation mechanism and the determination of the stress intensity factors. For example, preexisting pores would act as stress concentrators which might lead to more vulnerability to further crack growth. Moreover, the mode of crack propagation (transgranular and/or intergranular path) in polycrystalline materials depends on the normalized grain strength, normalized grain toughness and the presence of toughening mechanisms in the process zone (e.g., grain bridging or transformation toughening) which can reduce the stress intensity at the crack tip.

Despite its importance, there is not much literature about the microstructural influences on the mixed mode failure. In the study of mixed-mode fracture of ceramic materials, there is considerable heterogeneity among the investigations. For starters and factors to be considered are different types of ceramic materials (e.g., glasses, polycrystalline and monocrystalline ceramics), various kind of specimens and load configurations (e.g., three-point bending, asymmetric four-point bending, diametral compression, semi-circular bending, asymmetric semi-circular bending and Arcan test) and diverse types of cracks and notches (e.g., indentation surface flaws, edge-notch, central-crack and edge-crack). So, nowadays no conclusive results are found concerning the superiority of any given test for establishing a possible relationship between the best fitting fracture criterion and the microstructure of the materials. Nevertheless, it is important to mention that some microstructural effects are consistent between studies, for example polycrystalline ceramics exhibit higher normalized mode II fracture toughness than glasses due to crack-surface resistance from grain interlocking and abrasion, and fine-grained ceramic materials exhibit more reproducible mixed-mode data and fit better to brittle fracture theories when precracks are long enough to be free of the influence of the notch-tip field.

A propagating crack will follow the path of least resistance, i.e., maximum driving force, and if the material is isotropic and homogeneous, the crack will propagate to maximize the energy release rate, as occurs in glass. In contrast, the driving force for crack propagation will be reduced if there is any interaction between the growing crack and the microstructure that could absorb part of the energy available at the crack tip stress field. This is the case of toughened ceramics. When a specimen is tested in pure mode I loading, the crack propagates in its original direction, but in mixed-mode loading, the crack kinks out of the plane (Anderson, 2017). Thus, an important characteristic that allow to detect mixed loading conditions failure in a material is the presence of a crack deflection in the fracture surface. Two types of deflection can be observed: (1) tilting of the crack about an axis parallel to the crack-front and (2) twisting about an axis normal to the crack-front. The overall deflection process is manifested as roughness of the final fracture surface. Also, it has been reported an increase of fracture toughness that will depend on the twist component, the volume fraction and the shape of the particles (Green *et al.*, 2018). An important microstructural observation during brittle fracture is to determine the process zone, which is the area around the crack tip inside the material that is damaged due to localized large strains. In ceramic materials, the process zone is an area containing numerous microcracks. As the applied load is increased, the microcracks get denser until the zone is saturated, and the brittle failure commences. Some studies have reported an empirical relationship between the grain size of the material and the size of the process zone (Ayatollahi and Aliha, 2011; Ghouli *et al.*, 2018).

Fractography as post-mortem analysis of fracture surfaces is a powerful tool to evaluate fracture of glasses and ceramics. It could be used to identify the cause of failure and provide information about loading conditions. It is well known that fracture surfaces of brittle materials, like glass, will display 3 distinctive zones: (1) "the fracture mirror", defined as a relatively smooth region surrounding the fracture origin, (2) "the mist" which is the area with tiny local crack perturbations surrounding the origin and (3) "the hackle", defined by a region with out-of-plane perturbations as "fingers". An important factor of fractography studies is pattern recognition (Anderson, 2017). Unlike the case of mode I loading, it has been reported that when the glass is tested under mixed-mode loading, specifically in modes I/II, "the mist zone" does not form around glass fracture mirrors and the boundary is comprised of a "lance hackle zone" that is very similar to twist hackle. However, the size of the mirror region is not altered by the

mixed-mode loading conditions. These observations have a practical approach to distinguish between pure tension fracture surface (mode I) from a mixed-mode situation (Quinn, 2016).

Some microstructural effects described in the literature on glasses and ceramic materials, evaluated under mixed-mode fracture conditions, are:

- Studies on borosilicate glass revealed crack branching, primarily due to the formation of mixed-mode stresses at the crack tip during generation of the initial fracture. The crack branching pattern was analyzed, using fractal methods, and it was found variations of the fractal dimension depending on the stress level and the loading configurations (Chen *et al.*, 2015; DeLellis *et al.*, 2020).
- Fractography evaluations of soda-lime-silica glass and mica glass ceramics under mixed-mode I/II loading revealed absence of the mist region and the presence of twist-hackle markings in the fracture surface, as mentioned before, which could be used to identify surfaces of brittle materials that fail in combined mode loading. Also, the angles of branching could provide information about the state and direction of stress application (Freiman and Mecholsky, 2019).
- Texturized dental lithium disilicate (LS2) glass-ceramics, tested under combined mode-I and mode-II loading, showed an anisotropic fracture behavior, in which the crack path was redirected by the microstructure for long extensions of crack growth before reorienting toward the angle dictated by the fracture criterion. In this case, it was presumed an underlying competition between the energetically favorable path, induced by the microstructural texturization, governing the initial portion of crack growth, and the global mechanical driving force, leading the rest of the crack trajectory (Belli *et al.*, 2017).
- Mixed-mode fracture of hot-pressed Si_3N_4 was conducted using inclined indentation surface flaws in bending and large crack geometries in combined tension/torsion. Mixed-mode I/II fracture behavior of surface flaws was significantly different from that of large cracks. Surface flaws response was best described by coplanar fracture and strain energy density criteria, while large cracks behavior was best illustrated by non-coplanar fracture and maximum stress criteria. These findings suggest that shear resistance effects operate to reduce the effective value of the mode II stress intensity factor. To improve agreement between theory and experimental data, it was proposed a modified form of mode II stress intensity factor considering ratio of crack opening displacement (*COD*) to crack surface asperity height (*d*), where *d* is a function of material grain size. Results suggest that ceramics with high elastic moduli and large grain sizes may be the most susceptible to shear resistance effects (Petrovic, 1985). Tikare and Choi (1993) proposed that the toughening mechanism for silicon nitride materials, in mode I loading, is crack deflection by pullout of long needle-shaped grains, as well as crack bridging in the crack wake. Under combined mode I/II and pure mode II loading, the same toughening mechanisms are operative.
- Suresh *et al.* (1990) evaluated polycrystalline Al_2O_3 under mixed-mode I/II and I/III loading conditions. The mode of failure in both pure mode I and pure mode II loading was, predominantly, intergranular with sporadic transgranular cleavage. A similar failure mechanism was observed on the combined mode I/II fracture surfaces. In contrast, pure mode III fracture surface exhibits intergranular fracture as well as debris particles, flat transgranular facets, spanning tens of grains and abrasion marks produced by the severe frictional sliding between fracture surfaces. Combined mode I/III fracture exhibits similar trends. Additionally, it was observed that fine-grained polycrystalline alumina ceramic showed more reproducible mixed-mode toughness values in comparison to coarse-grained microstructure. Fine-grained microstructure minimizes possible crack bridging and microscopic deflections in crack path which might enhance frictional locking between the fracture surface asperities under near mode II loading conditions.
- Singh and Shetty (1989) evaluated CeO_2 -TZP materials and found that intergranular fracture was the predominant failure mode when the specimens were subjected to pure mode I loading. On the contrary, when the mode of failure was preponderantly pure mode II loading it was found to be transgranular. Also, it was found an increased mode II fracture toughness attributed to grain interlocking and abrasion observed by fractography techniques of fracture surfaces. Equivalent results were found by Ghoul *et al.* (2018).

Summary

Nowadays, most of mixed-mode loading evaluations performed in glasses and ceramic materials are conducted on biomaterials and structural products. After what was presented in this up-to-date review, it is clear the need for both a deep the state-of-the-art (including Mode III) studies that will bring standardized testing methods, and the inclusion of advanced analysis techniques (software and finite element analysis) that will achieve better adjustments between theoretical models and experimental data.

Acknowledgments

The authors wish to thanks Dr. I. LLatas for her contribution and useful comments and to Eng. R. Santiago for graphical support.

Introduction

Materials from any moving device or component are subjected to the risk of fatigue failure due to the growth of preexisting flaws, or cracks originated by the operating conditions. If the loading is below the material strength and occurs just once, it will, probably, not represent a risk of failure. Nevertheless, in real-world service, ceramic devices are frequently bearing small loads recurrently. Each repetition of a load could provoke progressive crack propagation generating, eventually, a crack-length long enough to induce failure of the component. In this case, it is common that failure is not preceded by large plastic deformation, even in ductile materials, rendering it more difficult to detect component damage under recurrent loads. Consequently, this phenomenon greatly increases the possibility of catastrophic failure at stress levels considerably below the strength of the material. For this reason, it is decisive to understand the behavior of ceramic materials under cyclic loading conditions.

It has been extensively documented the term “fatigue” to identify the deterioration of a material exposed to ongoing loading repetitions for sustained periods of service. In this process, the recurrent loading could be static or cyclic, and there are excellent textbooks dedicated to both topics (“Further Reading”). Here, special emphasis will be placed on cyclic fatigue. A basic distinction, though, should be made between “cyclic fatigue”, dependent on the cyclic nature of loading, and the “static fatigue” which is a constant-stress phenomenon.

Another relevant indication is the well-documented behavior of ceramics, known as the “slow-crack-growth” which generates an increase of the applied stress intensity factor until failure is reached. This subcritical crack propagation mechanism, in most cases, involves a stress-assisted reaction in liquid-containing environments that provokes dissolution at the crack tip of the amorphous phases. This mechanism is denoted as “delayed failure”, “stress corrosion” or “static fatigue”. Even though both terms could be confusing, what should be remembered is that despite the origin of the stress, when cyclic loading is applied, fatigue damage may result (Further Reading).

From this point forward, the term “fatigue” will be used to refer to “cyclic fatigue” or “mechanical fatigue”. The phenomenon is directly evaluated by the following stress parameters: minimum stress (σ_{min}), maximum stress (σ_{max}), stress amplitude (σ_a), stress range ($\Delta\sigma$), mean stress (σ_m), and the period (T), which correlates to one cycle or alternation of load and is associated to the number of stress cycles (N) and time (t), as shown in the following equations:

$$\sigma_a = \frac{\sigma_{max} - \sigma_{min}}{2} \quad (1)$$

$$\Delta\sigma = \sigma_{max} - \sigma_{min} = 2\sigma_a \quad (2)$$

$$\sigma_m = \frac{\sigma_{max} + \sigma_{min}}{2} \quad (3)$$

$$t = NT \quad (4)$$

Another important descriptor of the cyclic fatigue is the “R-ratio” (R) defined in Eq. (5)

$$R = \frac{\sigma_{min}}{\sigma_{max}} \quad (5)$$

The R -ratio could also be described in terms of stress intensities factors (K), a well-known parameter described in the literature (“Further Reading”). The stress intensity factor for the cyclic loading ($K(t)$) is associated with the applied load ($\sigma(t)$), a geometric factor (Y), and the length of the crack (a), by the widely known Eq. (6)

$$K(t) = \sigma(t)\sqrt{\pi a}Y \quad (6)$$

At this point, it is important to remember that subscript I is added to the stress intensity factor (K) to indicate that crack opening is occurring under mode I loading, i.e., pure tension across the crack face. Other ways to apply stress to cracks, as defined by Irwin (1958), are mode II (in-plane shear) and mode III (out-plane shear). However, the predominant situation for ceramics and glasses is mode I loading, so when no aperture mode is designated, mode I should be assumed. Thus, when a device is working under mode I cycling loading, the stress intensity factor could be re-written, for a time varying stress, $\sigma(t)$, as in Eq. (7):

$$K_I(t) = \sigma(t)\sqrt{\pi a}Y_I \quad (7)$$

Hence, $K_I(t)$, maximum and minimum, could be determined as in Eqs. (8) and (9)

$$K_{max} = \sigma_{max}\sqrt{\pi a}Y \quad (8)$$

$$K_{min} = \sigma_{min}\sqrt{\pi a}Y \quad (9)$$

in which (K_{max}) and (K_{min}) are the maximum and minimum values of stresses in cyclic loading, respectively. From Eqs. (8) and (9) it is clear that the R -ratio can be written as $R = \frac{K_{min}}{K_{max}}$. Furthermore, the cyclic stress intensity factor (ΔK) for a given cyclic loading with constant amplitude, could be defined by Eq. (10):

Fig. 1 Parameters associated to cyclic fatigue: (a) descriptors of cyclic loading and (b) Elber's approach to cycling loading.

$$\Delta K = K_{max} - K_{min} = (\sigma_{max} - \sigma_{min})\sqrt{\pi a Y} \quad (10)$$

Finally, a relationship between the cyclic stress intensity factor (ΔK) and the R -ratio (R) for cyclic fatigue phenomenon is exhibited in Eq. (11):

$$\Delta K = (1 - R)K_{max} \quad (11)$$

Another basic concept from linear elastic fracture mechanics (LEFM) should be considered: when a crack reaches a critical size, it becomes unstable and it propagates; then, K turns into K_{IC} or "fracture toughness". In addition, when the cyclic stress intensity factor reaches a critical level, i.e., K_{max} is equivalent to K_{IC} , then, Eq. (11) becomes Eq. (12) (Rösler *et al.*, 2007):

$$\Delta K_{IC} = (1 - R)K_{IC} \quad (12)$$

An important approach for cyclic stress loading, first proposed by Elber (1970), is referred to as the "crack closure" effect. He described material's behavior associated with opening and closing of cracks under cyclic loads. Paradoxically, the "crack closure" process is the incomplete closure of the crack during the unloading part of the cyclic fatigue. For this reason, some authors have suggested the name of "residual crack opening", which seems phenomenologically more appropriate than the "crack closure". Anyhow, since Elber, various researchers have found that, effectively, the "crack-closure" happens during crack propagation of a material subjected to cyclic fatigue. During the discharge cycle, a zone in compression close to the crack tip remains, creating a "crack-closure effect". The partial or insufficient closure of the edges of the crack makes an irreversible strain of the crack surfaces. Subsequently, during the loading cycle, this deformation allows debris to locate inside the crack, preventing complete closure of the crack, and promotes, at some point, the advance of the crack opening (Anderson, 2017). Elber defined K_{op} as the "crack opening stress intensity factor", and the ΔK_{eff} has the "effective cyclic stress intensity factor", which corresponds to the loading beyond which the crack is completely opened. The relationship is expressed in Eq. (13) (Richard and Sander, 2016).

$$\Delta K_{eff} = K_{max} - K_{op} \quad (13)$$

Another relevant parameter for cycling loading is the "fatigue-crack-growth threshold" (ΔK_{th}) that determines the limits for crack propagation, i.e., the crack will propagate if the cyclic stress intensity factor exceeds the fatigue-crack-growth threshold value ($\Delta K \geq \Delta K_{th}$). The threshold parameter is characterized by Eq. (14) (Rösler *et al.*, 2007):

$$\Delta K_{th} = K_{op} - K_{min} = (1 - R)K_{op} \quad (14)$$

Fig. 1 illustrates parameters associated with cyclic fatigue at constant amplitude, in Fig. 1(a) detailed descriptors of the cyclic loading while Fig. 1(b) shows crack propagation parameters.

Cyclic Fatigue Evaluation and R -Ratio Effect

Despite the importance of failure by cycling loading for certain applications, literature about evaluation of ceramics under these conditions is not abundant. Several reasons could account for this fact, such as the large number of samples required to obtain a reliable predictor of failure, the number of competing theories and unanswered questions in the field, among others. In any case, fatigue phenomenon is, in general, characterized by two approaches: (1) the well-known $S - N$ diagrams in which applied stress is plotted against the number of cycles and (2) the fatigue crack growth rate curves (FCGR), where crack growth rate is exhibited as a function of the stress intensity factor. Both cases will be addressed below.

Stress-Cycles Curves

The most common tool to evaluate fatigue phenomenon for materials are the so-called $S - N$ curves or Wöhler plots. These are diagrams representing the applied cyclic stress versus the number of cycles to failure. In the $S - N$ diagrams, the stress can be logarithmically or linearly represented while the number of cycles to failure will always be in logarithmic scale. To obtain these curves, a sample is cyclically loaded at a particular stress level, and the number of cycles to failure is registered. After several tests, recorded data is presented in a graph like the one shown in Fig. 2. Two distinctive regions are described for $S - N$ curves: low-cycle fatigue (LCF) field, where the number of cycles to failure is below 10^4 , and the high-cycle fatigue (HCF) area where the number of cycles exceed this value (Further Reading).

Dependence of stress with the number of cycles is quite clear in Wöhler diagrams: as the number of cycles increases, the applied stress supported by specimens is lower. Two distinguishing fatigue degradation patterns have been reported: some ceramics, like material A in Fig. 2, exhibit an horizontal asymptote which is associated with a parameter named “fatigue limit”, “fatigue strength” or “endurance limit” ($\Delta\sigma_0$). The endurance limit implies that from this level of stress and below, failure will not occur under a large number of stress-cycles. In other words, even if there is an increasing number of cycles, the stress range for failure will be, approximately, the same. Another behavior is the one displayed for material B in Fig. 2, which presents ongoing degradation while increasing the number of cyclic loading (Rösler *et al.*, 2007; Taylor, 2007; Pelleg, 2014).

Obviously, variations in the applied stresses will produce modifications of R -ratio that, accordingly, will generate changes in the Wöhler diagrams, as displayed in Fig. 3. It can be observed a downward shift of the curve when the R -ratio is increased, i.e., as its value is augmented, the failure of the component will occur at lower applied stress, for the same number of fatigue cycles (Taylor, 2007).

Fig. 4 exhibits several $S - N$ curves of ceramic materials compiled from different bibliographic sources. Two major trends could be identified: (1) those materials that behave as described in Section “Stress-Cycles Curves”, i.e., materials that follow the typical

Fig. 2 Typical $S - N$ curves with endurance level and low-cycle and high-cycle zones.

Fig. 3 Effect of R -ratio in $S - N$ curves.

Fig. 4 $S - N$ curves of some ceramics from several references.

$S - N$ curve; this is the case of composites and zirconia-based materials (3Y-TZP and 3Y-TZP/Ta), and (2) compounds with a linear behavior that is almost asymptotical to horizontal axis, which is the case of alumina and silicon nitride. It must be mentioned that Fig. 4 was constructed with data from various references, therefore, comparison of similar compounds is not straight forward. Data from different studies come with variations in: tests conditions (with or without indentation, humidity, etc), raw materials (grain size, commercial, etc.) and testing methods (flexural, rotary bending, etc.). In any case, all the materials shown in Fig. 4 have been used for many years within engineering components subjected to cyclic loading conditions, due to their good performance, high stress resistance, and other factors, such as cost and raw materials availability.

$S - N$ diagrams are very useful to study fatigue behavior but they require a large number of samples to obtain a representative graph. In this context, Goodman representations is a good approach to overcome the problem of high number of tests. Goodman graphs are created by plotting the stress amplitude versus the mean stress over a specified number of cycles. A continuous line is drawn between fatigue strength (σ_e) at $R = -1$, at mean stress equal to zero, and tensile strength (σ_u) at zero stress amplitude with $R = 1$. This results in a negative slope given by the expression displayed in Eq. (15) (Pelleg, 2014):

$$\sigma_a = \sigma_e \left[1 - \frac{\sigma_m}{\sigma_u} \right] \quad (15)$$

Any combination of amplitude and mean stress in this line will have the same fatigue life. Usually, the area below the curve is associated with conditions where the material should not fail, as shown in Fig. 5(b). The area outside the shaded triangle represents the probability of the occurrence of fatigue failure. As can be seen in Fig. 5(a), different R -ratios can be represented in the same diagram, and clearly, each one of them will modify the safe region of the component. The integers next to the symbols indicate the number of samples tested (Pelleg, 2014). Even though the Goodman diagram is widely used for metallic materials, some researchers had reported Goodman graphs for ceramic materials. Fig. 5(a) outlines the Goodman plots for 3Y-TZP (Liu and Chen, 1991a) and for Si_3N_4 (Soma et al., 1988; Masuda et al., 1990). In Fig. 5, the square and the circular dots allude to the experimental values for 3Y-TZP and Si_3N_4 , sequentially. The empty forms represent failed specimens under specific conditions, while the filled ones did not fail during the test.

Fatigue Crack Growth Rate Curves (FCGR Curves)

To study the relationship between fatigue crack-growth rate and R -ratio, it is necessary to point out that when a crack is subjected to fatigue by loading in pure mode I , propagation will occur in the initial direction of the crack, and the advance will continue, under the right conditions ($\Delta K \geq \Delta K_{op}$), as the load cycles are augmented. Thus, the mean crack-growth rate, within a time interval ($\Delta a / \Delta N$), will be associated with changes in crack length (Δa) per variations in cycle numbers (ΔN).

When ΔN tends to zero ($\Delta N \rightarrow 0$), the crack-growth rate will be equivalent to the slope (da/dN) of the crack length curve (a) versus the number of cycles (N), as shown in Fig. 6. Consequently, the crack growth rate accelerates exponentially with an increasing number of load cycles, for loading at constant amplitude. Therefore, as seen in Fig. 6, at constant R -ratio, the load applied to a cracked component generates a variation on the $a - N$ curve and, ergo, on the crack growth rate. Under greater loads ($\sigma_1 < \sigma_2 < \sigma_3$), the crack growth rate increases, and it becomes unstable at shorter crack lengths (Richard and Sander, 2016). Likewise, it is observed that with increasing R ($R_1 < R_2 < R_3$), the crack length also raises; consequently, the slope becomes steeper, which is associated with a higher crack propagation rate. Microscopical observation is the most common method to measure the crack length, among other techniques. Typically, studied samples consisted of edge-notched three- and four-point bending bars, compact tension specimens, double-cantilever beam samples and sometimes, double torsion probes (Munz and Fett, 2001).

Fig. 5 Goodman diagrams for ceramic materials from various references.

Fig. 6 Effect of R -ratio on fatigue crack-growth rate.

Normally, the crack-growth rate is found experimentally and is used to represent the fatigue crack growth behavior in a log-log plot of da/dN versus ΔK , which is a sigmoidal curve containing three distinctive regions (see Fig. 7). In this type of graph, two asymptotes can be observed: one for low ΔK values previously named ΔK_{th} or “fatigue-crack-growth threshold”, below which the crack will not grow; and one for the upper limit ΔK_{IC} where crack propagation becomes unstable, leading to fatigue failure. It is well documented that ceramic materials fracture in brittle manners with little or no signs of plastic deformation. Therefore, fracture origin is surrounded by a smooth area, called the mirror, and by rougher regions named the mist and the hackle. The sizes of these regions are proportional to σ^2 , where σ denotes the stress in an uncracked body at the position of the origin of fracture (Danzer *et al.*, 2008) (“Further Reading”).

The stages of crack growth rate associated with damage evolution are the following:

- (1) Stage I (crack initiation): consists of the development of microstructural damage such as microcracks, which will grow and eventually unite to form a dominant crack. Much of a component life can be spent at this stage if the conditions of the component are adequate.
- (2) Stage II (linear crack propagation): in this region, the dominant crack will grow stably under repeated applied loads at a rate following a power-law.
- (3) Stage III (unstable crack propagation): here, the crack has grown to a point where it becomes unstable, thereby accelerating, even more, the propagation of the crack, exposing the component to catastrophic failure.

In the linear region of the log-log plot in Fig. 7 (Stage II), the crack-growth rate follows the so-called “Paris law” (Paris and Erdogan, 1963), their empirical power-law relationship is shown in Eq. (16)

$$\frac{da}{dN} = C\Delta K^m, \quad (16)$$

Fig. 7 Typical log fatigue crack-growth behavior (FCGR curve).

where $\frac{da}{dN}$ represents the crack-growth rate, C is a constant depending on the material and the R -ratio, m is an exponent associated with the material's nature, and ΔK the cyclic stress intensity factor whose general definition is in the Eq. (11) ("Further Reading").

It has been found that the Paris exponent (m) for ductile metals takes values about 2–4, while for polymers it is ~ 10 . For brittle materials, such as ceramics the m -values are much larger, in the order of 10–100 (Kruzic et al., 2018). Thus, mechanistically, there are important differences between metals and ceramic materials. Experimental observations have demonstrated that crack-advance in ceramics is identical for cycling and for monotonic loadings, i.e., strongly dependent on stress intensity factor at the crack-tip (K_I). So, the stress intensity factor leading to fatigue failure (K_{max}) should be considered for ceramics in the empirical Paris law. In other words, the distinction between m values, for metals and ceramics, imply that crack-growth rates in ceramic materials will rely on K_{max} while metals will be more sensitive to ΔK . Some researchers modified Paris's empirical statement using Walker's model, which was originally designed for metallic materials. In this way, another observational growth-rate relationship that explicitly incorporates the effect of K_{max} , was developed. The modified relation is shown in Eq. (17): (Liu and Chen, 1991a; Dauskardt et al., 1992; Ritchie, 2003).

$$\frac{da}{dN} = C' (K_{max})^n (\Delta K)^p, \quad (17)$$

where, C' , n , and p are constants defined by $C' = C (1 - R)^n$ and $m = (n + p)$. Also, from Eq. (11) $K_{max} = \frac{\Delta K}{(1-R)}$; and hence, re-writing crack-growth rate in terms of R -ratio, the relation becomes: (Dauskardt et al., 1992; Ritchie, 2003)

$$\frac{da}{dN} = \frac{C'}{(1-R)^n} (\Delta K)^{(n+p)}. \quad (18)$$

This model has been reported to describe R -ratio effects of cyclic fatigue in technological ceramics like SiC-whisker-reinforced alumina composites in which the exponents n and p are ~ 10 and 5, respectively (Dauskardt et al., 1992). Another study for yttria-stabilized tetragonal zirconia polycrystal material (3Y-TZP) revealed m -value ~ 24 (Liu and Chen, 1991b). Equation (18) had been used for identifying dominant stress parameters under fatigue failure and, accordingly, to discriminate possible mechanisms for crack advance. For instance, it has been described that high values of m -exponent, in ceramics, are associated with extrinsic mechanisms conducting to fracture under cyclic loading, and it is characterized by higher n -exponent than p -exponent. On the contrary, in metals, frequently occurs a dominant dependence of ΔK , as a consequence of intrinsic mechanisms for crack propagation and weaker variation with K_{max} ; thus, p -exponent has larger values than n -values (Ritchie, 2003).

Another relevant consideration is the effect of R -ratio on typical log-log fatigue curves. It is shown in Fig. 8 how variations in R -values displace the sigmoidal fatigue curve. According to Eq. (14), there is a linear relationship between ΔK_{th} and the stress ratio, R -ratio, which can be seen in Fig. 8, i.e., the fatigue-crack-growth threshold is decreased when R -ratio values are increased. Accordingly, in the intermediate zone (stage II), the log-log curve goes towards higher values of da/dN , which means that the crack-growth rate accelerates as R increases. It is also evident from the graph in Fig. 8, that R -value influence is more pronounced at high and low crack-growth rate ranges, zones I and III, respectively; yet, the effect is less sensitive on the linear region (stage II). In summary, if R -ratio increases, so do the crack growth rate, and it lowers both the fatigue threshold (ΔK_{th}) and the allowed cyclical stress intensity factor (ΔK_{IC}) (Rösler et al., 2007; Taylor, 2007; Huang and Moan, 2007; Richard and Sander, 2016; Perez, 2004). It is worth mentioning that intensity factors, including ΔK_{th} , are sensitive to many parameters like grain size, Young's modulus, and others. So, it is common to find scattered results even within the same class of material. Still, the equations are useful in estimating the order of magnitude of the threshold. Some models have been proposed to indicate the influence of R -ratio on the fatigue crack-growth threshold value (ΔK_{th}), but they have been designed and tested for metallic materials (Rösler et al., 2007; Richard and

Fig. 8 Effect of R -ratio on fatigue crack growth rate curves.

Fig. 9 Crack-growth curves (FCGR curves) of different ceramic materials.

Sander, 2016). Nevertheless, it would be interesting, in the near future, to apply them in ceramics, in the same way other empirical models had been adapted in the past.

Fig. 9 shows representative da/dN curves for various ceramic materials. It is clearly detected, in the graph, the characteristic steep slopes of large values of Paris's exponent (m) for this type of compounds. Higher slopes are associated with small crack initiation zones and with accelerated crack growth in the propagation field. This behavior reflects the gradual and slow deterioration of fatigue resistance due to cyclical loading; thus, for ceramic materials, crack initiation and propagation regions are not as distinguishable as they are for metals. In metallic devices, there is a clear differentiation, kind of inflection point, indicating meaningful crack length over long periods before the material reaches the critical value for failure that allows detecting the crack during regular inspection procedures (Rösler et al., 2007).

Crack Growth Mechanisms During Cycling Loading

Several crack propagation mechanisms have been reported for metals and for ceramic materials, specific for each one of them. In metallic materials, crack propagation is dominated by intrinsic mechanisms like plasticity-induced closure, roughness-induced closure, oxide-induced closure, closure induced by a viscous fluid, and transformation-induced closure. Intrinsic mechanisms imply that crack advance happens from the damage process in the crack-tip field, being particular to cyclic loading. On the other hand, crack advance, in ceramic materials, is managed by extrinsic mechanisms like crack deviations, generation of inelastic zones around the cracks, or by crack interactions due to sliding, bridging, and wedging phenomena, described later. Extrinsic mechanisms usually involve crack propagation ahead of the crack tip in a similar manner as that for monotonic loading. It has

Fig. 10 Schematic illustrations of toughening mechanisms in ceramic materials.

been reported that an important issue of the cyclic crack growth in ceramics is the degradation of the crack-tip shielding, specifically in high-toughened ceramic materials (Ritchie, 2003).

The propagation of cracks in metals is a phenomenon that has been exhaustively studied and it is associated with the movement of dislocation and consequent plastic deformation that occurs at the crack tip ("Further Reading"). However, for ceramics materials, the plastic strain is highly restricted at low temperatures, so cracks cannot grow through this mechanism. For this reason, it was believed that fatigue did not affect ceramics, until some investigations, carried out in the last decades revealed that some ceramic materials can fail due to the propagation of cracks under cyclic loading. In particular, it was described that extrinsic mechanisms, designed to increase toughening in the material, were responsible for reducing the driving force of crack growth when applying fluctuating stresses in the crack faces. Some of these mechanisms are illustrated in Fig. 10 (Rösler *et al.*, 2007; Casellas *et al.*, 1999; Ritchie, 2003).

As mention before, in the case of intrinsic crack propagation mechanisms in metallic materials the predominant term from the modified Paris's empirical law (see Eq. 16), is ΔK , i.e., $n \ll p$. Thus, in the intermediate range (stage II), expressing growth rates in terms of ΔK , will linearize the load-ratio dependence. On the contrary, in ceramic materials, the dominant term is K_{max} , i.e., $p \ll n$; so, normalization is achieved by characterizing the growth rates as a function of K_{max} . This distinctive difference is represented in Fig. 11.

Although many efforts have been made to explain the mechanisms of cyclic fatigue in various ceramics and glasses, some aspects remain unclear. One of the first studies conducted on cyclic loading of ceramic materials was the one done by Evans and Fuller (1974). They evaluated glass and porcelain and showed that crack growth does not significantly increase by the effect of cyclic fatigue. In that work, it was concluded that degradation was primarily due to static slow crack growth mechanism and mechanical fatigue was considered of minor significance in these materials (Evans and Fuller, 1974). Later on, other authors reported that advanced ceramics with a pronounced R-curve effect appear to have higher sensitivity to cyclic loads (Dauskardt *et al.*, 1987; Lathabai *et al.*, 1989; Grathwohl and Liu, 1991; Kishimoto, 1991). For instance, Dauskardt *et al.*, demonstrated the influence of cyclic loading on magnesium partially stabilized zirconia samples (Mg-PSZ). Their results, based on changes in the crack-growth rate, reported that, under cyclic loading conditions, crack propagation values were by 8 orders of magnitude above the expected value for static loading conditions. Furthermore, crack propagation happened at stresses below the threshold value reported for static fatigue (Dauskardt *et al.*, 1987; Steffen *et al.*, 1991).

Until today, cyclic fatigue failure has been shown in several structural ceramics including various zirconia composites, alumina, silicon nitride, and silicon carbide, among others. While strong toughened ceramics appears to be very vulnerable to cyclic fatigue degradation, in

Fig. 11 Illustrative diagram of the intrinsic and extrinsic mechanisms involved in cyclic fatigue-crack growth in metals and ceramics. Adapted from Ritchie, R., 2003. Cyclic loading and fatigue: Fatigue of brittle materials. In: Milne, I., Ritchie, R., Karihaloo, B. (Eds.), *Comprehensive Structural Integrity*. Oxford: Elsevier, pp. 359–376.

what is seemingly to be a contradictory fact, glasses and un-toughened ceramic materials are mainly not affected by cyclic fatigue. Indeed, in ceramic materials, the cyclic loading acts to diminish the shielding in the crack wake. Common degradation processes of extrinsic mechanisms described in the literature for ceramic materials are: (1) Crack bridging, that occurs when non-fracture obstacles (such as grains, precipitates, fibers, whiskers, among others) that act as ligaments opposing aperture of the fissure, are left behind in the propagation of the crack. Then, repeated opening and closing of crack surfaces under cyclic loads causes them to rub against each other and induces dissipating energy, wearing the surfaces of the crack, and, eventually, reducing the crack bridging effect. (2) Deviation of cracks in grain boundaries, which can also generate a similar effect than crack bridging. (3) Transformation toughening, such as in partially stabilized zirconia, where phase transformations arise near the crack-tip. The phenomenon has associated volume increments at the crack tip upon the destabilization of the tetragonal phase, so compressive stresses are generated and induce closure of the crack. This effect is also related to the formation of microcracks near the crack tip (Rösler *et al.*, 2007; Casellas *et al.*, 1999; Cotterell, 2010).

Ample studies have been dedicated to monolithic non-transforming ceramics in which the toughening is primarily due to grain bridging in the wake of the propagating crack. Evaluated materials include several qualities of alumina, Si_3N_4 , SiC, and aluminum titanate, in which the grain-bridging mechanism is the microstructural basis of the fatigue failure. This behavior is attributed to a degradation of the grain-bridging zone associated with frictional wear at the grain matrix interface, that enhance the crack-tip driving force locally (Gilbert *et al.*, 1995; Jacobs and Chen, 1995; Li and Guin, 1995; Bermudo *et al.*, 1997; Huh and Song, 1998; Huh *et al.*, 2000; Han *et al.*, 2001; Sonsino, 2003; Kruzic *et al.*, 2004; El Attaoui *et al.*, 2005; Kruzic *et al.*, 2005; El Attaoui *et al.*, 2006; Matsudaira *et al.*, 2009). Another paramount toughened ceramics that exhibit mechanical degradation under fluctuating loads are zirconia-based composites. Materials with transformation toughening like magnesia-partially-stabilized zirconia (Mg-PSZ), yttria-tetragonal zirconia polycrystal (Y-TZP), ceria-tetragonal zirconia polycrystal (9Ce-TZP), and others, where phase transformation occur near the crack tip, and cyclic fatigue damage is attributed to the formation of microcracks in the vicinity of the crack tip (Dauskardt *et al.*, 1987; Grathwohl and Liu, 1991; Hoffman and Mai, 1995; Hoffman *et al.*, 1996; Schmitt *et al.*, 1996; Chevalier *et al.*, 1999).

An interesting study conducted by Casellas *et al.*, evaluated alumina, zirconia-toughened-alumina (ZTA) and mullite by cyclic fatigue at constant amplitude. They reported that the following extrinsic mechanisms for toughening are susceptible to fatigue degradation: (1) Deviation of crack's path due to interaction with second-phase particles or grains requiring higher stress levels to maintain crack propagation, (2) Grain bridging by non-fractured obstacles (3) Energy dissipation process by microcracking and (4) Development of compressive stresses related to volumetric changes by transformation toughening.

A singular outcome from this research was that alumina and ZTA suffer degradation when subjected to cyclic fatigue but mullite did not present damage under the same testing conditions. Thus, it was confirmed that advanced ceramics with increased toughening are more prone to suffer deterioration under cyclic loading due to deterioration of shielding mechanisms at the crack-tip (Casellas *et al.*, 1999).

Cyclic Fatigue Phenomenon (*R*-Ratio) and Microstructural Effect

Dependence of physical and mechanical properties on microstructure is well known in materials science. The vast amount of experimental results suggests that resistance of the materials to the initiation and propagation of fatigue crack are significantly influenced by multiple microstructural factors. To mention a few: interatomic bonds linked to material stiffness; presence and

nature of precipitates/inclusions and distances between them; surface roughness; porosities; and grain size (François, 1989). Analogous to R , the microstructural parameters have a profound influence on stages I and III of the crack growth curve, as represented in Fig. 7, and a less pronounced impact in region II (Perez, 2004). It should be noted that when more than one parameter is modified simultaneously, the incidence of these factors on fatigue resistance is unpredictable. There may be synergistic or antagonistic effects, depending on particular conditions of test and material nature.

In ceramic materials, the morphology of cyclic fatigue fracture surfaces is almost identical to that obtained under monotonic loads, except for one subtle detail, which is the presence of small debris particles on the fracture surfaces. Furthermore, it has been reported that the crack propagation path and crack growth mechanism are indistinguishable under static or cyclic fatigue processes (Ritchie, 2003; Ritchie and Dauskardt, 1991; Quinn, 2016). The configuration of the crack wake surface is determined by the inter- or transgranular fracture mode. Fractographic and in-situ crack-path evaluations from the majority of studies claim that fatigue fracture in ceramics is intergranular. This represents a discontinuous process depending on relative orientation of the grain boundaries and microstructural homogeneity of the material. The subcritical crack propagation in the intergranular path occurs along the grain boundaries by the creation, growth and coalescence of microcracks in front of the crack tip. Clearly, the process of intergranular fracture will happen in materials where the intergranular phases are weaker than the grains. Also, some pull-out of grains from the bulk of the material and relaxation of residual stress could happen due to intergranular crack propagation.

However, the process described above does not represent the whole picture, Kawakubo and Komeya (1987) referred to a fatigue failure that consisted of intergranular crack propagation with partial transgranular path at perpendicular elongated crystals of sintered Si_3N_4 (Kawakubo and Komeya, 1987). Another study reported a fine-grained Si_3N_4 with transgranular propagation generating a flat fracture surface that did not present accelerated fatigue failure (Horibe and Hirahara, 1991). A singular evaluation, conducted on hard porcelain, revealed transgranular crack path after cyclic loading, basically due to heterogeneous microstructure (amorphous matrix, crystalline grains and porosities) (Maity *et al.*, 1994). In conclusion, there is not one single path for crack growth; it will depend on the specific microstructural features of each material. This fact was confirmed by a very interesting study conducted by Mutoh *et al.* (1993) on the fatigue crack growth rate (cyclic and static) of five ceramic materials: Si_3N_4 , Al_2O_3 , TiB_2 , SiC and ZrO_2 . Evaluations of the morphologies of the fractures surface revealed the following: (1) materials with predominantly intergranular fatigue-cracking exhibit microcracking at the crack tip with formation of bridging elements in the crack wake, but the bridging units located behind the crack tip tends to be broken; cyclic loading provokes degradation of shielding effect at the crack tip. (2) materials with mostly transgranular fatigue-cracking exhibit crack growth rate identical under static and cyclic loading conditions. A summary of these observations is presented in Table 1. (Mutoh *et al.*, 1993).

As expected, in cyclic fatigue studies, one of the most reported microstructural features is grain size, which significantly influences fatigue resistance in ceramic materials. An interesting approach could be to consider the empirical Hall-Petch relation where the mechanical resistance is inversely proportional to the square root of grain size. Even though the relationship is widely used in metallic materials, it has also been reported valid for ceramic materials like zirconia composites and magnesium aluminate spinel, specifically in hardness measurements (François, 1989; Pelleg, 2014). In any case, this empirical concept could be used over the cyclic fatigue resistance since fine-grained microstructures exhibit superior fatigue properties over coarse-grained materials, assuming all other microstructural features are kept, approximately, fixed. In this context, the research of Grathwohl and Liu (1991), confirms this approach. They evaluated the effect of grain size on fatigue resistance for tetragonal zirconia material stabilized with ceria (9Ce-TZP). Three different grain sizes were studied (1.0, 1.5 and 2.7 μm) and the results were presented as stress-failure time curves (useful life). It was determined that stress required to produce fatigue failure decreased with increasing grain size, regardless of magnitude of R -ratio (See Fig. 12). In the same work, an important microstructural observation was that fatigue samples with larger grain sizes evidenced higher degree of transcrystalline fracture probably due to the tetragonal to monoclinic transformation within the grains for this 9Ce-TZP ceramic material. (Grathwohl and Liu, 1991; Pelleg, 2014).

Notable appreciation from Fig. 12 is the comparison of the material under static or cyclic loading. It is revealed for 9Ce-TZP that under static loads, failure times are about 2 or 3 orders of magnitude higher than for cyclic loading, at the same stress level (Grathwohl and Liu, 1991). This fact has been recognized by other studies, like the one conducted by Dauskardt *et al.* (1990), that reported crack growth improvements up to 8 orders of magnitude by cyclic fatigue compared to static loading for an evaluation done in partially stabilized zirconia with magnesium oxide (Mg-PSZ).

Table 1 Morphologies of the fracture surfaces under cyclic fatigue

Material	Fracture path
Si_3N_4	Intergranular
SiC	Transgranular
TiB_2	Intergranular and transgranular
ZrO_2	Transgranular
Al_2O_3	Intergranular and transgranular

Fig. 13 Effect of grain size in crack growth rate for Si₃N₄ and Al₂O₃. Adapted from Mutoh, Y., Hansson, Y.T., Takahashi, M., 1995. Effect of grain size on fatigue crack growth in silicon nitride and alumina. In: Bradt, R., Brookes, C., Routbort, J. (Eds.), *Plastic Deformation of Ceramics*. New York: Springer, pp. 653–666.

On the other hand, microstructural effects on cyclic loading is not a simple issue and dependence of fatigue crack propagation threshold on the grain size, for instance, is a little more complex situation. In this regard, a study was conducted on two ceramic materials (Si₃N₄ and Al₂O₃) with different grain sizes (designated as “small” and “large”). In **Fig. 13**, the results of crack propagation rate as a function of ΔK , are presented. For coarse-grained Si₃N₄ (see **Fig. 13**) higher threshold value (ΔK_{th}) and lower crack propagation rate (da/dN) were found, compared to the values of finer Si₃N₄. Specifically, the threshold value increased from 2.9 MPa^{1/2} for the small grain to 4.7 MPa^{1/2} for the large grain size material. Similar behavior was observed in alumina. Possible explanations for this behavior could be: (1) incomplete crack closure during unloading due to high degree of roughness in the crack surface that will generate increments in the closing load, i.e., (K_{op}), and, consequently, it will increase (ΔK_{th}) according to Eq. (14), and (2) raise of the grain bridging effect, which is a very important crack-tip shielding mechanism, due to higher grain sizes in the material. It has also been reported that materials with intergranular fracture, like the one from this study, show an increasing R-curve behavior with increasing grain size (Mutoh *et al.*, 1995; Gilbert and Ritchie, 1997).

In conclusion, there is a need for systematic investigations of cyclic fatigue for a large group of ceramic materials. Some reported results could be applied only to a particular kind of ceramic material and they could not be considered as common characteristics of ceramics. Furthermore, other aspects such as variable amplitude of the cycling loading, high temperature fatigue and thermal fatigue are interesting topics to examine but they are beyond the scope of the present article. In any case, systematic studies are required for a better understanding of fatigue crack-growth phenomena.

Cyclic Fatigue (R-ratio) and Ceramic and Glasses Applications

Through the years, enhanced properties of advanced ceramics have introduced them into new fields of applications including environmental uses, energy, biomaterials composites, intelligent materials, and so on. Proper functioning of materials in these areas must take into account operating conditions that could promote cyclic fatigue of ceramic devices. In this regard, it is handy to remember the evaluation of advanced ceramics under cyclic loading conditions: alumina, silicon nitride, lead zirconate titanate, and zirconia-based materials, are prone to undergo accelerated degradation, while ceramics like soda-lime glass, porcelain, silicon carbide, mullite, lead titanate, and α -alumina, are not. This susceptibility to cyclical fatigue is associated with deterioration of shielding mechanisms, mainly bridging and weakening for microcracking, which allows crack propagation reactivation (Evans and Fuller, 1974; Kishimoto, 1991; Guiu *et al.*, 1991; Liu and Chen, 1991a; Ritchie and Dauskardt, 1991; Horibe and Choi, 1994; Casellas *et al.*, 1999).

Thus, to conclude the present article, it is worthwhile to mention some practical applications and studies related to engineering ceramics subjected to cyclic loading. One example is the use of alumina in automobile spark plugs and hip joint replacements (Sômiya *et al.*, 2003; Matizambuka, 2018). A very important field of development is the utilization of zirconia-based compounds with different oxide stabilizers for dental restorations, particularly in dental pieces such as crowns or bridges. Other outstanding applications for zirconia-based materials are components for the aerospace industry, cutting and drilling tools and biomedical implants. Latest research in this area reported materials that include metallic ductile phase in the matrix of zirconia composite (ZrO_2 -Ta) to increase fracture toughness, tolerance to damage and fatigue performance (Dauskardt *et al.*, 1990; Grathwohl and Liu, 1991; Guiu *et al.*, 1991; Liu and Chen, 1991a; Schmitt *et al.*, 1996; Anglada *et al.*, 2002; Delgado *et al.*, 2003; Chevalier *et al.*, 2007; Wang *et al.*, 2014; Smimov *et al.*, 2017; Gjurin *et al.*, 2018; Matizambuka, 2018; Belli *et al.*, 2020; Chevalier *et al.*, 2020; Wei *et al.*, 2020).

Another relevant ceramic is silicon nitride for its excellent properties. This type of compounds is employed for engine and turbine components, such as turbocharger rotors or bearings, valves and cutting tools in industrial environments. Nowadays, it is common to find them as refractory materials, exposed to temperature fluctuations during production cycles, inducing cyclical thermomechanical loads. Recent study has described the use of silicon-based material as spring material for aggressive high-temperature conditions, in combination with humid environments under cyclic loads. Even though, thermal fatigue is out of the scope of this article, it should be considered for future fatigue studies (Ritchie and Dauskardt, 1991; Jacobs and Chen, 1995; Bermudo *et al.*, 1997; Sômiya, 2013; Andreev *et al.*, 2018; Khader *et al.*, 2020).

Finally, a paramount material that has caught attention for several years is the lead zirconate titanate (PZT). This material is attractive as ferroelectric ceramic and even now is being studied for the electric voltage effect generated under cyclic loads over long periods (Kishimoto, 1991; Weitzing *et al.*, 1999; Okayasu and Ogawa, 2020). Although it is out of the scope of this article, it is advisable to consider, in the forthcoming times, the cyclic fatigue of ferroelectric and piezoelectric ceramics, mainly in electric and electronic devices. This is an interesting closed-related field of study that will enhance the knowledge of the fatigue behavior of ceramics under cyclic loads.

Acknowledgments

The authors wish to thank Dr. I. LLatas for her useful comments and to Col. A. Gutiérrez-Campos for graphical support.

Thermal Properties of Ceramic Materials

Introduction

Ceramic materials constitute one of the very important classes of material that mankind exploits in the modern world. The abilities of ceramic materials to control heat exchange and resist high temperatures explain why they are used in the building, cooking, electronics, aerospace, transport, and energy sectors. In such working situations the thermal properties become of prime importance. These are essentially heat capacity, thermal expansion and thermal conductivity. Though related parameters such as thermal diffusivity can be considered, the present contribution focuses on these three properties.

In this context, the notions of temperature and heat energy can be introduced. Starting from the zero'th law of thermodynamics, temperature is a parameter which determines whether a system is in thermal equilibrium with another system. At the microscopic scale, temperature corresponds to a measure of the average energy or thermal agitation of the atoms. Heat is then a form of energy associated with the movement of individual atoms or molecules of a body (gas, liquid, or solid) and is defined from the first law of thermodynamics as energy in transit due to a difference in temperature. Heat capacity refers to the heat energy required to increase the temperature of a body and, in experimental conditions of constant volume, is related to the change in internal energy. For a typical ceramic material, the internal energy U expresses itself in the form of atomic vibrations. At higher temperature a larger amplitude of vibrations occurs corresponding to higher internal energy.

If two systems are at different temperatures then heat transfer can take place by conduction, convection or radiation. According to the second law of thermodynamics, heat flows from the hot body to the cold body or surroundings. The focus here will be on conduction in the solid state which can be described for heat flow in one dimension down a thermal gradient by Fourier's law

$$\Phi = -\lambda A \frac{dT}{dx} \quad (1)$$

where Φ is heat flow in W, A is the cross sectional area, T is temperature, and x is a position coordinate within the solid body. In the case of a homogeneous isotropic solid, λ corresponds to a constant of proportionality in Eq. (1) known as the thermal conductivity. In a ceramic material the heat energy is carried by the atomic vibrations which determine λ .

Thermal expansion or contraction can also be related to the nature of atomic vibrations in the solid. Increase in volume of a solid at higher temperature can be explained by the increased amplitude of vibrations about an average position. But since in the interatomic pair potential the repulsion and attraction terms are not symmetric, the average atomic separation increases for the larger amplitude vibrations at high temperature.

Given the importance of atomic vibrations for all three properties, the first section discusses lattice vibrations in a crystalline solid.

Lattice Vibrations

Consider a single atom vibrating in a solid (Fig. 1). If it is connected to the surrounding atoms with a force constant equivalent to Young's modulus, the natural vibration frequency is of the order of 5×10^{12} Hz.

This is equivalent to frequencies in the infrared. But the stimulation of vibrations in a crystalline solid involves a much wider range of frequencies from sound waves at low frequencies below 1 kHz up to the THz region. This is because the solid is a multi-atom system. It is conveniently treated as a continuum.

Consider now a line of atoms connected by springs representing the chemical bonds. Propagation of a vibration takes place in the form of an elastic wave described, for example, by a cosine function:

$$u(x, t) = u_0 \cos(qx - \omega t) \quad (2)$$

where ω is the radial frequency and $q = \frac{2\pi}{\Lambda}$ is proportional to the inverse of the wavelength Λ .

Two types of waves can be identified:

- Transverse waves where atoms move at 90° to the propagation direction,
- Longitudinal waves where atoms move in the same direction as the propagation direction.

For a given elastic wave propagation direction, two transverse polarizations at 90° to each other and one longitudinal polarization are required to describe the movement of an atom in any direction in space (i.e., the description is complete).

So the vibrational modes of the crystal can be described in the form of elastic waves each with a characteristic wavelength and frequency. Two questions can then be asked:

- (1) How many vibrational modes (or different waves) exist?

Fig. 1 Simple representation of a single atom vibrating in a solid.

Fig. 2 Single particle on a tight string.

Fig. 3 Three particles on a string – different vibration modes.

Consider identical atoms in a line oscillating in the form of transverse standing waves. By analogy to a particle on a string of length L , a system with one free atom has one mode of oscillation with wavelength $2L$ and a characteristic frequency (Fig. 2).

Now consider three atoms in the line (or three particles on a string). Three different modes of oscillation with wavelengths: $2L$, L , $2/3 L$ can be identified (Fig. 3).

So each new atom adds a new mode of oscillation. For N atoms, there will be N modes of oscillation. If the three types of polarization are then taken into account this gives for a crystal with N atoms a total of $3N$ modes of vibration.

(2) What is the relation between wavelength and frequency?

Consider a crystal of identical atoms with cubic symmetry. The atoms on a line, each separated by distance a , are connected with bonds represented by springs which obey Hooke's law. When an atom is displaced from its equilibrium position (u_s), the restoring force is proportional to the displacement distance. The equation of motion can be written:

$$M \frac{d^2 u_s}{dt^2} = \sum_p K_p (u_{s+p} - u_s) \quad (3)$$

where each atom has mass M , K_p is the force constant on atom s due to the relative displacement between atoms $s+p$ and s . With simplifications this has solution:

$$\omega = \left(\frac{4K_1}{M} \right)^{1/2} \left| \sin \left(\frac{1}{2} qa \right) \right| \quad (4)$$

where K_1 is the nearest neighbor force constant and q is the inverse wavelength (Kittel, 1976). Eq. (4) describes theoretically the dispersion relation between frequency and inverse wavelength for what are known as acoustic vibrations. In this type of vibration the atoms (even if of different type) move in phase with each other. The physically useful solutions are found in the

Fig. 4 Dispersion relation in the first Brillouin zone for a simple system with identical atoms.

range $-\pi/a < q < +\pi/a$; known as the Brillouin zone (Fig. 4). At low frequency, the wavelength is long (small value of q). At high frequency (q tends to $\frac{\pi}{a}$), the wavelength is short and approaches the interatomic distance, a .

In fact the derivative (slope) of the dispersion relation $\frac{d\omega}{dq} = v_g$ is the group velocity of the elastic waves or close to the origin, the speed of sound in the crystal. This is an important factor for heat conduction through the crystal.

Finally, we should consider what happens to the vibrational possibilities of the solid when the crystal structure (unit cell) involves two or more different atoms, as in the case of MgO. The result is that the dispersion relation develops new branches at high frequency called optical branches. These vibrations are more complex than acoustic vibrations because the different atom types vibrate in opposition of phase. Though the optical branches have important effects, especially for infrared absorption, the present discussion can be restricted to the acoustic branches with respect to heat capacity and thermal conductivity.

Heat Capacity

Heat energy is defined from the 1st law of thermodynamics given by:

$$\Delta U = Q + W \quad (5)$$

where ΔU is the internal energy change, Q is the heat transferred to system and W is the work done on the system. The first law expresses the conservation of energy in a process and allows the notion of heat capacity to be introduced. Heat capacity is defined by the heat energy required to increase the temperature of a body by 1K according to the experimental conditions of constant volume or constant pressure. For constant volume

$$C_V = \left(\frac{dQ}{dT} \right)_V = \left(\frac{\partial U}{\partial T} \right)_V \quad (6)$$

where T is temperature, U is the internal energy and subscript V refers to constant volume.

For a system at constant pressure (example: solid in a chamber with a controlled pressure but no control on volume):

$$C_P = \left(\frac{dQ}{dT} \right)_P = \left(\frac{\partial H}{\partial T} \right)_P \quad (7)$$

where H is the enthalpy and subscript P refers to constant pressure.

For solids $C_P \approx C_V$ except at high temperature. So C_V can be calculated which is easier and C_P is measured corresponding to real experimental conditions. We focus on the internal energy U of a solid. Starting at a minimum energy state (the ground state) at absolute zero ($T = 0$ K), the increase of internal energy with temperature is expressed in different ways:

- Atomic vibrations,
- Excitation of electrons to higher energy levels,
- Formation of defects, which increases the disorder of the solid.

If the solid is electrically insulating, like many ceramics and glasses, there are very few available conduction electrons. So the major contribution to the internal energy comes from the atomic vibrations. This allows a simple but very useful model as a first approximation to be developed.

High Temperature Limit of Heat Capacity (or Classical Model)

Consider an atom in a crystal lattice (solid) which can move in one direction. This is a 1 dimensional simple harmonic oscillator (like a ball on a spring). For vibration in 1 direction, from the equipartition theorem, there is:

- $\frac{1}{2} k_B T$ of average kinetic energy (due to particle speed).
- $\frac{1}{2} k_B T$ of average potential energy (stored energy).

where k_B is Boltzmann's constant. As the atom vibrates to and fro these energy modes are continually exchanging. The total average energy for the atom is then the sum, i.e., $k_B T$. However in a solid an atom moves in 3 dimensions. So we require three orthogonal directions (x, y, z) to describe its movement completely. Since each direction has an energy of $k_B T/\text{atom}$, the total average energy is $3k_B T/\text{atom}$.

For N atoms in the solid the energy content is:

$$U = 3Nk_B T \quad (8)$$

So the heat capacity is:

$$C_V = \frac{dU}{dT} = 3Nk_B \quad (9)$$

which is just a constant value (invariant with temperature). This result can be used to illustrate another important point. As listed below heat capacity comes in different forms.

Heat capacity	per unit mass	$[\text{JK}^{-1} \text{kg}^{-1}]$	$C = \frac{1}{m} \frac{dQ}{dT}$ where m is the sample mass
	per unit volume	$[\text{JK}^{-1} \text{m}^{-3}]$	
	per mole	$[\text{JK}^{-1} \text{mole}^{-1}]$	
	per g – atom	$[\text{JK}^{-1} \text{g – atom}^{-1}]$	

In each case to calculate C_V with Eq. (9) it is necessary to count the number of atoms in the unit of a kg , m^3 , mole or g-atom . As an example, 1 g-atom contains N_A atoms where N_A is Avogadro's number (6.02×10^{23}). So the heat capacity per g-atom is approximately $25 \text{ J K}^{-1} \text{g-atom}^{-1}$ and this is independent of the type of solid (Kingery *et al.*, 1976).

In fact Eq. (9) is a good approximation of the high temperature behavior of many crystalline solids but does not describe the lower temperature behavior. Experimentally as temperature tends to absolute zero ($T = 0 \text{ K}$), the heat capacity decreases to zero. So what is missing? It is the collective nature of atomic vibrations in the form of elastic waves which has not been taken into account. The simple classical model considered each atom as moving individually without affecting the neighbors. In fact as the solid is cooled, it contracts with shortening of the atom-atom nearest neighbor distances. If one atom moves, it pushes or pulls its neighbors. So instead of adding up the energies of each atom, the Debye model is based on the sum (or in practice the integral) of the energies of these collective vibrations.

Debye Model

In the standard treatment made in solid state physics textbooks (Kittel, 1976) a number of simplifications are made: first a monatomic solid with cubic symmetry is considered with N atoms contained in a volume V . All the elastic waves are assumed to move with the same speed (of sound), i.e., the dispersion relation is linear (called the Debye approximation: $\omega = v_0 k$). Then the energy of each elastic wave is quantified: $\xi = (n + \frac{1}{2})\hbar\omega$, where $\hbar\omega$ is the smallest interval of energy called a phonon by analogy to the photon.

Instead of counting up the energy of all the atoms, the energies of all the possible elastic waves (vibrational possibilities of solid) are counted up to a maximum limiting frequency, called the Debye frequency (ω_D). This yields the well known Debye expression for heat capacity.

$$C_V = 9Nk_B \left(\frac{T}{\theta_D} \right)^3 \int_0^{x_D} \frac{x^4 e^x}{(e^x - 1)^2} dx \quad (10)$$

where $x = \frac{\hbar\omega}{k_B T}$, $x_D = \frac{\theta_D}{T}$, and $\theta_D = \frac{\hbar v_0}{k_B} \left(\frac{6\pi^2 N}{V} \right)^{1/3}$ is the Debye temperature.

Plotting this relation yields a heat capacity starting at 0 at $T = 0 \text{ K}$ which increases with T (Fig. 5). However at high temperature C_V then approaches a constant value. This high temperature limit is the same value as that predicted by the simple classical model. In the low temperature regime, close to $T = 0 \text{ K}$, C follows a dependence $\propto \left(\frac{T}{\theta_D} \right)^3$. This describes all the main features of heat capacity as a function of temperature. And though most solids are not quite as simple as the monatomic cubic crystal, Debye's model predicts values close to experimental data (Kingery *et al.*, 1976).

In practice the temperature dependence of heat capacity for a solid is described by a polynomial relation with a set of empirical coefficients. This is illustrated in the following example for alumina ceramic.

Example

Suppose we wish to calculate how much energy a furnace must supply to heat up alumina to a firing temperature of 1800 K (close to 1500°C).

The heat capacity per unit mass over this range can be described by a polynomial relation:

$$C = \frac{1}{M} \left[a + bT + \frac{d}{T^2} \right] \quad (11)$$

Fig. 5 Debye model – Heat capacity per $3 NK_B$ as a function of temperature (T/θ_D).

Fig. 6 Thermal expansion of ceramics. Data from Kingery, W.D., Bowen, H.K., Uhlmann, D.R., 1976. Introduction to Ceramics, second ed. New York: John Wiley and Sons.

where a , b , d are empirical coefficients ($a = 117.487$, $b = 10.376 \times 10^{-3}$, $d = -3.711 \times 10^6$ for alumina) found in a thermochemical data handbook (Knacke *et al.*, 1991) and M is the molar mass.

The energy change is obtained by integrating the polynomial relation in Eq. (11)

$$\Delta E = \int_{300}^{1800} C(T) dT = \frac{1}{M} \left[aT + \frac{bT^2}{2} - \frac{d}{T} \right]_{300}^{1800} \quad (12)$$

$$\Delta E \simeq 1.79 \text{ MJ kg}^{-1}$$

Thermal Expansion

Linear thermal expansion of a solid is characterized by measurements of length (dimension), denoted by l , as a function of temperature. Some typical curves for ceramic materials, which can be considered as macroscopically isotropic, are given in Fig. 6.

The expansion results from the asymmetry of the interatomic pair potential where the repulsion term is stronger than the attraction term holding the atoms in the solid together. The coefficient of thermal expansion (α) is then given by:

$$\alpha = \frac{1}{l_0} \frac{dl}{dT} \quad (13)$$

where l_0 is the reference length chosen at a convenient temperature such as 0°C . The coefficient α increases with temperature but, similarly to heat capacity, tends towards an asymptotic value as shown in Fig. 7.

In fact, the average separation distance of atoms at a given temperature is determined by the energy of the atomic vibrations. So similar trends in the coefficient of thermal expansion and heat capacity can be explained by the role of atomic vibrations.

In practice, thermal expansion coefficients are often evaluated as average values between 0°C and 1000°C ($\bar{\alpha}$). Thus a useful approximation for length l is given by:

Fig. 7 Coefficients of thermal expansion for alumina and magnesia. Data from Kingery, W.D., Bowen, H.K., Uhlmann, D.R., 1976. Introduction to Ceramics, second ed. New York: John Wiley and Sons.

Table 1 Mean thermal expansion coefficients between 0°C and 1000°C for some ceramic materials

Material	Average linear thermal expansion coefficient ($\bar{\alpha}$ with units K^{-1})
Alumina	8.8×10^{-6}
Magnesia	13.5×10^{-6}
Mullite	5.3×10^{-6}
Stabilized zirconia	10.0×10^{-6}
Silicon Carbide	4.7×10^{-6}
Diamond	3.5×10^{-6}

Note: Data from Kingery, W.D., Bowen, H.K., Uhlmann, D.R., 1976. Introduction to Ceramics, second ed. New York: John Wiley and Sons.

$$l = l_0(1 + \bar{\alpha}T) \quad (14)$$

where T is in °C. For larger temperature ranges or greater accuracy, polynomial relations are used as given in the Handbook of Physics and Chemistry (Rumble, 2018):

$$l = l_0(1 + aT + bT^2 + cT^3 \dots) \quad (15)$$

where a , b , c are empirical coefficients and T is in °C.

One can also consider the coefficient of volume expansion (β) given by

$$\beta = \frac{1}{V_0} \frac{dV}{dT} \quad (16)$$

where V is the volume of the solid and V_0 is the volume at 0°C. For isotropic expansion

$$\bar{\beta} \approx 3\bar{\alpha} \quad (17)$$

provides a useful approximation.

Average values for linear thermal expansion coefficient of some well known ceramic materials measured for a temperature change between 0°C and 1000°C are given in Table 1 (Kingery *et al.*, 1976).

They can be compared to values for metals like copper of $16.6 \times 10^{-6} K^{-1}$ or aluminum of $25 \times 10^{-6} K^{-1}$. It can be noted that solids with strong covalent bonding such as diamond or silicon carbide exhibit small values of linear thermal expansion coefficient. The role of bond strength in a solid is also revealed by the relation of crystal symmetry to linear thermal expansion coefficients measured along the different crystal axes. Some relevant examples are given in Table 2.

The case of graphite is a good illustration with strong anisotropic thermal expansion due to the weak bonding between graphite planes compared to the bonds within the plane.

Anisotropic thermal expansion of individual grains has another consequence. If the polycrystalline matrix of a sintered ceramic consists essentially of random orientations, cooling down to room temperature after firing will yield stresses. For a significant difference in coefficients along the crystal axes combined with large grains, this can result in microcracking (Kingery *et al.*, 1976). Such behavior is revealed by hysteresis in the dilatometric curve of Fig. 8.

One solution to avoid this consists of careful powder preparation and processing to limit grain size. For example, alumina ceramics, made with an average grain size of less than 10 μm , do not exhibit microcracks.

Table 2 Thermal expansion coefficients measured perpendicular and parallel to the c-axis

Crystalline Solid	α measured normal to the c-axis (units K^{-1})	α measured along the c-axis (units K^{-1})
Alumina (Sapphire)	8.3×10^{-6}	9.0×10^{-6}
Silica (Quartz)	14.0×10^{-6}	9.0×10^{-6}
Graphite	1.0×10^{-6}	27×10^{-6}
Aluminum Titanate	-2.6×10^{-6}	11.5×10^{-6}
Titania	6.8×10^{-6}	8.3×10^{-6}

Note: Data from Kingery, W.D., Bowen, H.K., Uhlmann, D.R., 1976. Introduction to Ceramics, second ed. New York: John Wiley and Sons.

**Fig. 8** Dilatometric heating and cooling curve with hysteresis due to microcracking.

Intrinsic Thermal Conductivity

Heat conduction through an isotropic solid is proportional to the thermal gradient applied across it, described by Fourier's law as given in Eq. (1). In a dielectric solid (like most ceramics) where there are no mobile electrons, this heat is carried by the atomic vibrations discussed earlier. Imagine these vibrations traveling in different directions through the solid. Sometimes they collide setting off new vibrations in new directions with new energies (called 3 phonon or 4 phonon processes). This behavior is like that of a gas and so we consider the vibrations as a gas of "phonons". From kinetic theory the thermal conductivity of an ideal gas can be described with the relation:

$$\lambda = \frac{1}{3} C \bar{v} l \quad (18)$$

where C is the volume heat capacity, $\bar{v}$ is the root mean square speed of the gas molecules and l is the mean free path of a molecule between collisions.

In a somewhat similar way the thermal conductivity of the phonon gas is described by

$$\lambda = \frac{1}{3} \int_0^{\omega_D} c(\omega) v(\omega) l(\omega) d\omega \quad (19)$$

where c , v and l refer to heat capacity, group velocity and mean free path of the lattice vibrations. These are all dependent on frequency (ω) and with the integral we add up all the acoustic vibrational contributions from low or sonic frequencies up to the Debye frequency in the THz region. The Debye frequency marks the highest frequency which can be excited.

Two important questions can then be asked about thermal conductivity.

- (1) How does it vary with temperature for a crystalline inorganic non-metallic solid?
- (2) How does it vary between different types of solid such as crystalline and amorphous solids?

The following examples help to give some answers.

Example 1

Consider the thermal conductivity of an alumina single crystal (sapphire) measured as a function of temperature. In fact most crystalline dielectric solids follow the general behavior of a peak value in λ at low temperature at about 20 K and notably a progressive decrease as temperature is increased to about 1000°C (Fig. 9).

Fig. 9 Thermal conductivity as a function of temperature for a crystalline solid.

Fig. 10 Schematic of thermal conductivity as a function of temperature for a crystalline solid compared to a glass such as two different forms of silica.

We must examine the three parameters c , v and l found in the integral of Eq. (19). Since the propagation speed of the vibrations only decreases slightly as temperature is increased, in a first approximation, $v(\omega)$ is considered as a constant. At the lowest temperatures (left hand side of the peak value), the mean free path of the lattice vibrations is of the order of the sample size (i.e., mm). The principal controlling variable is the heat capacity which follows T^3 behavior as mentioned in the previous section. This explains why at absolute zero ($T = 0\text{K}$), the thermal conductivity tends to zero because there are no excited vibrations to carry heat.

As T increases, the heat capacity asymptotically approaches a constant value (above room temperature). This means for the high temperature side of the peak, the principal controlling factor is the mean free path. In essence as more lattice vibrations are stimulated at higher temperature, they mutually interfere; thus shortening the mean free path. At 1000°C the mean free path approaches the interatomic distance of less than 1 nm. This explains the dramatic decrease in thermal conductivity for single crystal alumina (sapphire) from $5000\text{ W m}^{-1}\text{ K}^{-1}$ at low temperature (about 20 K) to typically less than $7\text{ W m}^{-1}\text{ K}^{-1}$ at 1000°C (Kingery *et al.*, 1976); i.e., almost 3 orders of magnitude. At room temperature a single crystal of alumina (Sapphire) exhibits a typical value of $36\text{ W m}^{-1}\text{ K}^{-1}$ (Popov *et al.*, 2011).

Example 2

The role of the mean free path can be illustrated in another way when two forms of silica are compared. These are:

- (a) Crystalline solid (quartz),
- (b) A glass.

The thermal conductivity of quartz is greater than glass for all temperatures (Fig. 10). This is essentially due to a difference in mean free paths. In a glass, the mean free path for propagation of vibrations is restrained to approximately the interatomic distance due to the lack of order in the structure (disordered solid). Thus the thermal conductivity of a glass, typically close to $1\text{ W m}^{-1}\text{ K}^{-1}$, actually increases slightly with temperature, following the variation of the heat capacity. It can also be seen how at high temperature the conductivity curve of quartz approaches that of a glass – because the mean free path tends towards the interatomic distance.

Fig. 11 Pores, grains and grain boundaries in tin oxide ceramic.

This section has emphasized the role of the mean free path of atomic vibrations in the intrinsic thermal conductivity of a material. In the final section modulation of this value by the microstructure to yield an overall (or effective) thermal conductivity for the ceramic materials is discussed.

Influence of Microstructure on Thermal Properties

Compared to a single crystal, ceramic materials are characterized by the presence of grain boundaries and pores (Fig. 11). In the case of a composite material, the ceramic is also constituted by a mixture of solid phases, each one with its own properties. So the question to ask is: What is the effect of this microstructure on the heat capacity and thermal conductivity? These microstructural factors are examined in the order:

- Grain boundaries,
- Pores,
- Mixture of solid phases.

Heat Capacity

The heat capacity of a dielectric solid is essentially controlled by the atomic vibrations and depends on the number of atoms contained in the chosen unit of study (a mole, a kg, or a m^3). Though increased disorder will increase the internal energy, the effect of a grain boundary on heat capacity can be neglected since there is virtually no change in the number of atoms in the mole, the kg, or the m^3 .

Using the same approach, the presence of porosity in the ceramic material does not change the number of atoms in a kg of solid. Therefore the heat capacity per unit mass (specific heat denoted by C) of dense alumina is the same as that of porous alumina. In contrast the heat capacity per unit volume of porous alumina (ρC with units $\text{J K}^{-1} \text{m}^{-3}$) is less than that of dense alumina because there are fewer atoms in 1 m^3 of the material. This is exploited in furnace design when rapid heating or cooling is required. Furnaces can be made of very porous refractories with small values of heat capacity per unit volume.

Ceramic materials, such as many refractories, often present a mixture of two or more solid phases. In such a case an average value (C_{av}) representing the material can be calculated using the rule of mixtures:

$$C_{\text{av}} = m_1 c_1 + m_2 c_2 \quad (20)$$

where m_1 , m_2 are the mass fractions and c_1 , c_2 are the specific heat values of phases 1 and 2. The rule of mixtures (or Neumann-Kopp rule) also offers a valuable approximation in the case of an unknown phase providing it can be broken down into constituents with known specific heat values. This can avoid the need to make delicate experimental measurements.

Fig. 12 Schematic of local thermal conductivity and temperature variation for three grains in the heat flow path.

Thermal Conductivity

The effects of microstructure are particularly significant for the thermal conductivity. First consider heat transfer by conduction across grain boundaries. The presence of local disorder in the grain boundary region increases the scattering of the lattice vibrations, yielding a local decrease in thermal conductivity. Thus interfacial thermal resistances can be attributed to the grain boundaries which act as additional series resistances in the heat flow path to those of the grains (Smith *et al.*, 2003). Due to the pronounced temperature drops occurring in conditions of steady state heat flow, illustrated in Fig. 12, the interfacial resistances are also called Kapitza resistances.

The thermal conductivity of the dense polycrystalline ceramic can now be described by the expression:

$$\frac{1}{\lambda_{\text{poly}}} = \frac{1}{\lambda_{\text{grain}}} + nR_{\text{int}} \quad (21)$$

where n is the number of grain boundaries per unit length of heat flow path (or inverse grain size) and R_{int} is the grain boundary thermal resistance. Typical values for R_{int} are in the range $0.5\text{--}1.0 \times 10^{-8} \text{ m}^2 \text{ K W}^{-1}$ depending on the material (Smith *et al.*, 2003, 2018, 2013).

As an example single crystal alumina (or sapphire) has a thermal conductivity of $36 \text{ W m}^{-1} \text{ K}^{-1}$ at room temperature. In its polycrystalline form, alumina with an average grain size of $1 \mu\text{m}$ yields a value of λ_{poly} close to $30 \text{ W m}^{-1} \text{ K}^{-1}$ and with an even smaller average grain size of $0.5 \mu\text{m}$, the effective thermal conductivity of dense alumina is less than $25 \text{ W m}^{-1} \text{ K}^{-1}$ (Smith *et al.*, 2018).

So smaller grain size of a ceramic reduces its effective thermal conductivity. Though, that said, the effect is less significant for insulating materials like stabilized zirconia where the thermal resistance of the grains is predominant.

The role of porosity on the effective thermal conductivity (λ) of a ceramic is now examined. Theoretically, the effective thermal conductivity can be predicted using a 2-phase mixture approach with a choice of analytical relations differing by the geometrical simplifications which have been made (Fig. 13).

For small amounts of porosity $v_p < 15\%$, the pores are typically closed, and well isolated from each other. This can be approximated by a spherical void centered in a solid cube as described by the Maxwell-Eucken relation:

$$\lambda = \lambda_s \frac{\lambda_p + 2\lambda_s + 2v_p(\lambda_p - \lambda_s)}{\lambda_p + 2\lambda_s - v_p(\lambda_p - \lambda_s)} \quad (22)$$

where λ_s is the solid phase thermal conductivity, λ_p is the pore thermal conductivity and v_p is the pore volume fraction.

In fact in this range, most relations yield predictions which are close to each other as shown in Fig. 13 (Smith *et al.*, 2013).

For pore volume fraction $> 15\%$, typically the pores are connected or “open”. In this case, the pore phase blocks the heat transfer more effectively due to the spatial distribution and this can be described by Landauer’s relation based on effective medium theory (Landauer, 1952):

$$\lambda = \frac{1}{4} \left[\lambda_p(3v_p - 1) + \lambda_s(2 - 3v_p) + \left([\lambda_p(3v_p - 1) + \lambda_s(2 - 3v_p)]^2 + 8\lambda_s\lambda_p \right)^{1/2} \right] \quad (23)$$

A very nice agreement to Landauer’s relation is given by measurements of the thermal conductivity of porous zirconia ceramics made with latex pore formers as can be seen in Fig. 14 (Nait-Ali *et al.*, 2006).

Then as a final example of very porous materials, kaolin based foams present pore volume fractions upto 95% with large semi-closed pores as shown in Fig. 15 (Bourret *et al.*, 2013).

Fig. 13 Analytical relations describing thermal conductivity as a function of pore volume fraction for a porous solid. These are the Maxwell - Eucken (blue), the Rayleigh (orange), the Landauer (brown) relations and the lower Hashin-Shtrikman bound (gray). The solid phase conductivity has been fixed with a value of $\lambda_s = 5 \text{ W m}^{-1} \text{ K}^{-1}$.

Fig. 14 Effective thermal conductivity as a function of pore volume fraction for porous zirconia ceramics. Experimental values compared to predictions by the Maxwell-Eucken and Landauer relations.

Fig. 15 Microstructure of very porous kaolin based ceramics.

These in fact yield experimental conductivity values close to the Hashin - Shtrikman upper bound, which is equivalent to the Maxwell - Eucken relation. The comparison between prediction and experiment is presented in [Fig. 16](#). With 95% porosity, the conductivity is close to $50 \text{ mW m}^{-1} \text{ K}^{-1}$, just twice the thermal conductivity of air ([Bourret et al., 2013](#)).

As a final word, this approach of phase mixture relations can also be extended to mixtures of solid phases as found in composite materials such as many refractories.

Fig. 16 Effective thermal conductivity as a function of pore volume fraction for porous kaolin based ceramics. Experimental values compared to predictions by the Maxwell-Eucken and Landauer relations.

Conclusions

The thermal properties of a ceramic material are determined essentially by its atomic vibrations. Heat capacity for a crystalline solid can be related to the derivative with respect to temperature of the internal energy. The internal energy is dominated by the contribution of the lattice vibrations. Thermal expansion results from the asymmetry of the interatomic pair potential. Thus at higher temperature, larger amplitude vibrations yield an increase in average atomic separation. Finally, with application of a thermal gradient across a polycrystalline ceramic material, the majority of heat is carried by lattice vibrations. This intrinsic thermal conductivity can be significantly modulated at the macroscopic scale by the ceramic microstructure due to the presence of pores and grain boundaries.

Thermal Shock Behavior of Ceramics: Fundamentals and Thermal Shock Resistance Parameters

Carmen Baudín, Instituto de Cerámica y Vidrio, CSIC, Madrid, Spain

Introduction

Most applications of ceramics materials involve temperature gradients that vary over time. These gradients produce differential deformations in the components and, consequently, stresses (i.e., thermal stresses). If the stresses created exceed the fracture strength of the material, degradation or even complete failure occurs. Together with corrosion and abrasion, failure due to thermal stresses is one of the main mechanisms of degradation of many ceramic parts in service.

It is said that a body is subjected to thermal shock when the surrounding temperature changes sharply. The simplest example, found frequently in everyday life, is the case of a ceramic part that is cooled rapidly from a temperature, T_0 , to a temperature, T_f . The surface will tend to contract and its contraction will be prevented from the interior that is at a higher temperature. Therefore, surface tensile stresses develop and they might lead to fracture. The case in which the rate of temperature variation is infinite is the easiest case to deal with theoretically and, at the same time, the most extreme. The conclusions derived from this approach, modulated, are applicable to situations of milder temperature changes.

In this article, the general aspects of thermal stresses and fracture are discussed. It has been chosen to refer classical works that established the physics and mechanics of the problem during the second half of last century. The main material properties involved in the response to thermal shock and their relative influence are described in terms of the so-called *thermal shock parameters*. First, the two classic approaches to the problem of thermal shock resistance of brittle materials – thermoelastic approach and energy balance criterion – and the associated parameters are reviewed. Subsequently, the *Unified theory of Hasselman* and the derived parameters are discussed.

Finally, values of the properties involved in the thermal shock resistance of different materials are reported and the classification of ceramic materials in terms of the thermal shock parameters in order to check their suitability for different applications is discussed.

Thermal Stresses

Polycrystalline ceramics with non-textured microstructures can be considered at the macroscopic level as homogeneous and isotropic. Therefore, the magnitude of the expansion or contraction that a ceramic component undergoes when its temperature increases or decreases can be characterized by the coefficient of linear thermal expansion, α , determined from the unidirectional expansion suffered by an elongated specimen.

If a bar of length, L , and free ends is heated or cooled with a temperature increment, $\Delta T = T_f - T_0$, it will expand or contract for a length, $\Delta L = L_f - L_0$, given by Eq. (1):

$$\Delta L = \alpha \cdot L_0 \cdot \Delta T \quad (1)$$

The magnitude of ΔL varies depending on the material. For example, for 1 m long bars cooled from 125°C to room temperature (25°C), ΔL would be ≈ 0.5 and 13.5×10^{-4} m for silica glass and a magnesia refractory, respectively.

If the bar is prevented from deformation, it will be subjected to stresses which level is given by Hook's law (Eq. (2)):

$$\sigma = E \cdot \varepsilon = E \cdot \alpha \cdot \Delta T \quad (2)$$

Where:

$$\varepsilon = \frac{\Delta L}{L_0} \quad (3)$$

is the strain.

When the temperature of the surroundings of a component changes abruptly, an uneven temperature distribution is created across it. Then, a distribution of stresses arises due to incompatibilities between deformations originating in different areas of the piece. The simplest case is that of a thin plate of infinite length subjected to sudden cooling or heating from its surface (Fig. 1).

If the surface is instantly cooled from the temperature T_0 to T_f , a temperature profile develops such that, at the first instant, the surface is at T_f and the center of the plate at T_0 (Fig. 1(a)). The surface tends to contract, which is prevented by the interior, so a stress distribution is created that changes from compression to tension from the center of the plate to the surface. If the plate heats up instantly, the sign of the stresses is reversed (Fig. 1(b)).

Kingery (1959) and Kingery *et al.* (1976) summarized solutions for thermal stresses that develop due to sudden cooling in different simple geometric configurations. In cases where the temperature variation is instantaneous, the maximum surface tension can be described by expressions given by Eq. (4):

$$\sigma = C \cdot \frac{E \cdot \alpha}{(1 - \nu)} \cdot \Delta T \quad (4)$$

Fig. 1 Thin plate of infinite length subjected to a sudden temperature change from its surface. T_0 : initial temperature, T_f : final temperature. (a) Cooling. (b) Heating.

where C is a dimensionless factor that includes all the geometrical terms, ν is the Poisson's coefficient and $(1-\nu)$ accounts for the biaxial stress state.

In practice, temperature variations are not instantaneous, so the stresses created are lower than those calculated from Eq. (4) and vary over time. In the case where the coefficient of heat transmission between the surface of the specimen and the environment, h , is constant, the magnitude of the stresses can be expressed in terms of a dimensionless parameter called the Biot modulus (Eq. (5)) (Kingery, 1959; Hasselman, 1970):

$$\beta = \frac{\alpha \cdot h}{K} \quad (5)$$

where α is a characteristic dimension of the body in the direction of the maximum temperature gradient and K is the thermal conductivity of the material.

The maximum surface tension is reached after a certain time interval has elapsed, the greater the smaller the Biot modulus, and it is given by:

$$\sigma = \frac{E \cdot \alpha}{(1-\nu)} \cdot \Delta T \cdot f(\beta) \quad (6)$$

In general, $f(\beta)$ is a complicated function of the Biot modulus; however, different authors have established approximations for low values of the Biot modulus ($\beta < 5$) – i.e., low heat transmission, small parts or high thermal conductivity of the material. The general expression is given by Eq. (7) (Kingery, 1955; Hasselman, 1963a):

$$\frac{1}{f(\beta)} = A + \frac{B}{\beta} \quad (7)$$

where A and B are dimensionless constants.

The effect of Biot modulus is exemplified in Fig. 2, in which the maximum stress reached in a refractory lining is plotted as a function of time for two different values of β . It is important to emphasize that the stresses developed by a fixed temperature variation – i.e., the severity of the conditions to which a component is subjected – depend on the properties of the material, the heat transfer mechanism, the geometry of the component and the thermal gradient. The actual maximum stress is lower and it develops after longer times for lower β – i.e., low heat transfer to the environment, small characteristic dimension and higher thermal conductivity of the material.

As can be concluded from the above discussion, the level of thermal stresses developed in a ceramic component depends on the properties of the material, the conditions of heat transfer (magnitude and speed of temperature variation), and geometric factors (shape and size of the piece, orientation against the thermal gradient). Therefore, it is impossible to evaluate the thermal shock resistance of a material using a single property or test satisfactory for all conditions.

Variation of the Properties Due to Thermal Shock

When the stresses originated in a body by thermal shock equal or exceed the fracture strength of the material, σ_f , degradation by cracking occurs. Such degradation is reflected in the material properties, elastic, electrical, thermal, etc., and, especially, strength.

The general behavior of brittle materials subjected to sudden cooling of different severities, ΔT , is schematically represented in Fig. 3.

This graph shows the variation of strength of the material and summarizes both the classic experiments performed on alumina materials (Davidge and Tappin, 1967; Ainsworth and Moore, 1969) and subsequent experiments on various types of dense structural ceramic materials (e.g., Coppola and Bradt, 1973; Konsztowicz, 1990; Sato et al., 1987) and refractories (e.g., Maity et al., 1997). In these

Fig. 2 Maximum stress reached in a refractory lining as a function of time for two different values of the Biot modulus, β .

Fig. 3 General behavior of brittle materials subjected to sudden cooling as a function of the temperature difference, ΔT . ΔT_c and $\Delta T'_c$: minimum temperature differences for propagation of short and long cracks, respectively. σ_f and σ_r : Strength of the material before and after sudden degradation by thermal shock, respectively.

experiments, nominally identical specimens are subjected to cooling of increasing intensity and the strength is determined in flexure. Several regions are observed in the graph:

- (1) The strength of the specimens subjected to temperature variations of magnitude equal to or less than ΔT_c is the same as that of the untested specimens, σ_f .
- (2) The strength values of most specimens subjected to thermal shock of intensities close to ΔT_c , σ_r , are much lower than the original ones.
- (3) The increase in the intensity of the thermal shock from ΔT_c to $\Delta T'_c$ does not imply further degradation of the material.
- (4) From $\Delta T'_c$, strength experiences a gradual decrease as the severity of the shock increases.

From this figure, it is clear that there are two fundamental aspects to consider when dealing with the problem of thermal shock resistance. On the one hand, the beginning of the fracture for a ΔT_c and, on the other, the degree of propagation of the cracks once the fracture begins, which determines the degradation suffered by the material – i.e., difference between σ_f and σ_r .

Classic Models

Fracture under the sole effect of thermal shock occurs in absence of external body forces. Therefore, the only energy available for crack propagation is the elastic energy due to the thermal stresses build up in the body by the temperature change, which is finite. This fact makes the analysis of thermal shock different from the typical analysis of fracture in ceramic bodies subjected to constant applied stress.

The classic models that describe the thermal shock resistance of brittle materials are based on the simplification of the thermal state and the geometry of the body and provide parameters that weigh the relative effect of the intrinsic properties of the materials on the behavior – start and propagation of cracks – against temperature variations (Kingery, 1955, 1959; Kingery *et al.*, 1976; Hasselman, 1963a,b, 1969, 1970, 1971).

In essence there are two types of approach to the problem: the study of the beginning of the fracture, based on the results of the thermoelastic theory, and the study of the degree of damage suffered by the material due to the propagation of the cracks, from an energy balance criterion. The Hasselman (1969, 1971) Unified Theory encompasses both approaches and makes it possible to completely predict the behavior plotted in Fig. 3.

Thermoelastic Approach

The thermoelastic approach is essentially based on the calculation of the stresses created in a component or structure subjected to given thermal conditions. The criterion is that fracture occurs if the stresses created exceed the fracture strength of the material. This type of approach allows predicting which solicitations lead to fracture of the component or structure as a function of the properties of the material. Classical works collecting analytical expressions for the surface and volume stresses created in pieces of simple geometry (disks, spheres, etc.) subjected to thermal solicitations are those by Hasselman (1970) and Kingery (1955).

Resistance to thermal shock is defined as the minimum solicitation – temperature difference, rate of temperature change, etc. – required to develop a thermal stress equal to the fracture strength of the material. As discussed above, in the case of simple geometric shapes cooled through a certain, ΔT , the thermal stress created has the general form of Eq. (4), for infinite rate of temperature variation ($h = \infty$) and of Eq. (6) for mild conditions. Then, the fracture criterion is the minimum temperature interval, ΔT_c , that raises thermal stresses equal to the strength of the material.

In the case of $h = \infty$, from Eq. (4):

$$\Delta T_c = \frac{1}{C} \cdot \sigma_f \cdot \frac{(1 - \nu)}{E \cdot \alpha} \quad (8)$$

Different authors have proposed approximations that simplify Eq. (7) and give proportionality relationships between $f(\beta)$ and β . In such cases, for mild conditions of temperature variations, with $h = \text{constant}$, the critical temperature interval is given by Eq. (9):

$$\Delta T_c = \frac{1}{C'} \cdot \sigma_f \cdot \frac{(1 - \nu)}{E \cdot \alpha} \cdot \frac{K}{h \cdot a} \quad (9)$$

Where C' is a dimensionless constant.

The material properties included in Eqs. (8) and (9) can be grouped in two parameters called *thermal shock resistance parameters* for the initiation of fracture:

$$R = \sigma_f \cdot \frac{(1 - \nu)}{E \cdot \alpha} \quad \text{for } h = \infty \quad (10)$$

$$R' = \sigma_f \cdot \frac{(1 - \nu)}{E \cdot \alpha} \cdot K = K \cdot R \quad \text{for } h = \text{cte} \neq \infty \quad (10')$$

Energy Balance Criterion

In many cases, the working conditions are severe enough to produce fracture; therefore, it is necessary to know the degree of damage that the material will experience due to the fracture. This problem was studied by Hasselman (1963b) using results previously obtained by Kingery (1955) and an energy balance criterion.

When a solid is subjected to a sudden temperature change, non-compatible dimensional changes from different parts of the solid give rise to stresses within it and, consequently, to an increase in the strain energy. This strain energy is the only energy available for crack propagation. For ΔT_c the cracks in the body will grow absorbing the strain energy accumulated in it, converting the strain energy in surface energy. The final size of the cracks is dependent on their initial size and the number of cracks that propagate.

Even though it is not possible to perform an exact energy balance during the propagation of the cracks, it can be assumed the area of the new surfaces created to be proportional to the energy available for propagation, i.e., the strain energy.

The model used by Hasselman is a sphere of radius b with N identical cracks whose surface undergoes a sudden increase in temperature. It is assumed that cracks do not interact during propagation. The conclusions, in terms of material properties, can be generalized to other geometries using dimensional analysis.

At the point of fracture, the elastic energy accumulated in the piece is given by Eq. (11):

$$W_e = B \cdot \sigma_f^2 \cdot \frac{(1 - \nu) \cdot V}{E} \quad (11)$$

where V is the volume of the piece and B is a dimensionless constant.

The surface energy necessary to propagate N cracks through an area A is given by Eq. (12):

$$W_f = 2 \cdot A \cdot G \quad (12)$$

where G is the surface fracture energy required to produce unit area of crack surface. By matching Eqs. (11) and (12), it is possible to know the area through which the cracks would propagate (Eq. (13)):

$$A = B' \cdot \frac{\sigma_f^2 \cdot (1 - \nu) \cdot V}{N \cdot E \cdot G} \quad (13)$$

The area A would be minimized when the elastic energy – proportional to σ_f^2/E – is minimized and the effective surface energy and the number of cracks are maximized.

Therefore, the material properties can be grouped in the *thermal shock parameters for damage*, R''' and R'''' , whose maximization will minimize, damage (Eqs. (14) and (15)):

$$R''' = \frac{E}{\sigma_f^2 \cdot (1 - \nu)} \quad (14)$$

$$R'''' = \frac{E \cdot G}{\sigma_f^2 \cdot (1 - \nu)} \quad (15)$$

In order to maximize R''' and R'''' it would be necessary to maximize the Young's modulus while minimizing the fracture strength, which is somehow contradictory because in general strength and Young's modulus present similar trends when the microstructure is changed. This is why materials subjected to severe thermal shocks, sufficient to begin fracture, should present high values of the fracture energy.

Unified Theory of Hasselman

From the results of the thermoelastic theory, it is possible to predict the existence and evaluate the magnitude of the critical temperature interval, ΔT_c , or minimum temperature difference that causes the fracture of the material in Fig. 3. Moreover, the classical energy balance approach predicts the sudden degradation from σ_f to σ_r and evaluates the degree of damage suffered by the body. However, none of these two approaches has the remaining sections of the curve of Fig. 3 – range of ΔT originating the same degradation, additional critical temperature interval, $\Delta T_c'$, and gradual increase in the degree of damage for shocks of intensity greater than $\Delta T_c'$.

Hasselman's (1969, 1971) Unified Theory encompasses both the moment of initiation of fracture and the associated damage and allows to completely predicting the behavior of a brittle material under thermal shock shown in Fig. 3. The approach of this theory, based on a criterion of minimum energy, is similar to the one used by Griffith to study the fracture of brittle solids (Griffith, 1921).

In the first paper (Hasselman, 1969), the historical one, Hasselman takes as a model a body with N circular cracks per unit volume, which is prevented from contracting because its surfaces are rigidly held and which is cooled evenly. This model is the one that maximizes the severity because all the points of the body are subjected to a triaxial state of thermal stresses.

The two-dimensional model proposed by Hasselman (1971) is shown in Fig. 4. It is a plate infinite in the X direction of a brittle material containing N cracks of length, $2l$, per unit area. The plate is cooled uniformly while its deformation in the Y direction is prevented. This model is closer to the actual conditions of thermal shock because it can be assimilated to the surface of a suddenly cooled body. In addition, its mathematical treatment is simpler and the conclusions are similar to those of the original model.

It is assumed that fracture of the plate occurs by the simultaneous propagation of the N cracks when the temperature increment reaches, ΔT_c , and that the cracks do not interact.

The equilibrium state of an elastic body subjected to external forces is one in which the energy of the entire system is minimal. To use this theorem when studying the fracture of real solids, it is necessary to consider, in addition to the variation in elastic energy, the increase in energy involved in the creation of two new surfaces.

Fig. 4 The two-dimensional model used by Hasselman in 1971 (Hasselman, 1971). A plate infinite in the X direction of a brittle material containing N cracks of length, $2l$, per unit area. Deformation in the Y direction is prevented.

The Young's modulus of the cracked plate, E_{eff} , is given by (Eq. (16)):

$$E_{eff} = \frac{E}{(1 + 2\pi \cdot N \cdot l^2)} \quad (16)$$

where E is the Young's modulus of the material without cracks.

The elastic energy in the plate when it is uniformly cooled a temperature interval, ΔT , is given by (Eq. (17)):

$$W_e = \frac{\alpha^2 \cdot (\Delta T)^2 \cdot E}{2 \cdot (1 + 2\pi \cdot N \cdot l^2)} \quad (17)$$

The surface energy due to the presence of the cracks is (Eq. (18)):

$$W_s = 4 \cdot G \cdot l \cdot N \quad (18)$$

where G is the surface fracture energy required to produce unit length of crack. In the three dimensional model, G is the surface fracture energy required to produce unit area of crack surface, in the same way as in the energy balance criterion.

The total energy of the cooled cracked plate is given by (Eq. (19)):

$$W = \frac{\alpha^2 \cdot (\Delta T)^2 \cdot E}{2 \cdot (1 + 2\pi \cdot N \cdot l^2)} + 4 \cdot G \cdot l \cdot N \quad (19)$$

Thermal requirement for fracture onset

Cracks will be unstable whenever their growth diminishes the energy of the system ($dW/dl \leq 0$). The condition $dW/dl = 0$ allows determining the critical temperature interval (Eq. (20)):

$$\Delta T_c = \left(\frac{2 \cdot G}{\pi \cdot l \cdot \alpha^2 \cdot E} \right)^{\frac{1}{2}} \cdot (1 + 2\pi \cdot l^2) \quad (20)$$

The relationships between the critical temperature interval and the crack length are plotted in Fig. 5(a) (solid lines) for plates with two different crack densities.

For a given value of ΔT_{c0} , crack instability occurs between two values of crack length. The minimum value, l_0 , is coincident for both crack densities while the maximum one, l_1 and l_2 , is smaller for materials with higher crack densities. These observations can be quantitatively derived by using the approximations of short ($2\pi l \ll 1$) and long ($2\pi l \gg 1$) cracks, as described below.

The approximation of short cracks leads to a critical temperature interval independent of the density of cracks:

$$\Delta T_c = \left(\frac{2 \cdot G}{\pi \cdot l \cdot \alpha^2 \cdot E} \right)^{\frac{1}{2}} \quad (21)$$

while for long cracks, the critical temperature interval, $\Delta T'_c$, is a function of the density of cracks, N :

$$\Delta T'_c = \left(\frac{8 \cdot \pi \cdot G \cdot N^2 \cdot l^3}{\alpha^2 \cdot E} \right)^{\frac{1}{2}} \quad (22)$$

Taking into account the Griffith (1921) criterion for crack instability (Eq. (23)), it is possible to evaluate the relative effect of material properties on, $\Delta T'_c$ in the same way as for the previously discussed approaches. The bidimensional model leads to (Eq. (24)):

$$\sigma_f \approx \left(\frac{G \cdot E}{l} \right)^{\frac{1}{2}} \quad (23)$$

$$\Delta T_c \approx \frac{\sigma_f}{\alpha \cdot E} \quad (24)$$

And, in the tridimensional model:

$$\Delta T_c \approx \sigma_f \cdot \frac{(1 - \nu)}{\alpha \cdot E} = R \quad (25)$$

For long cracks, considering just the material properties involved in Eq. (22), it is possible to define this new thermal shock parameter that will optimize the behavior of materials with long cracks:

$$R_{st} = \left(\frac{G}{\alpha^2 \cdot E} \right)^{\frac{1}{2}} \quad (26)$$

Regions of crack instability

As plotted in Fig. 5(a), the $\Delta T - l$ plane is divided in two zones of stability and instability, delimited by the curve $dW/dl = 0$. The region of crack instability is larger for materials with low crack densities. As discussed above, for a given ΔT_{c0} , the fracture of the plates takes place if the size of the cracks is between two values of l . The minimum crack size, l_0 , that would result in the fracture of

Fig. 5 Main results from the Unified theory of Hasselman (Hasselman (1969, 1971)). (a) Normalized critical temperature interval vs crack length (solid lines) for plates with two different crack densities, N . I: instability. (b) Normalized critical temperature interval vs crack length (solid lines) for a plate with $N=10/2\pi$. When initially short cracks, $l_0 < l_m$, reach the region of instability, they propagate kinetically to reach l_f .

the plates is the same for both crack densities. However, the maximum crack size for instability for higher crack density, l_1 , is smaller than for lower crack density, l_2 .

Propagation of the cracks

Eq. (20) is not sufficient to completely describe crack propagation. The sign of d^2W/dl^2 determines the type of propagation the cracks, quasi-static ($d^2W/dl^2 > 0$) or kinetic ($d^2W/dl^2 < 0$); the limit is given by:

$$l_m = (6 \cdot \pi \cdot N)^{\frac{1}{2}} \quad (27)$$

Cracks with size $l_0 > l_m$ propagate in a quasi-static manner while when $l_0 < l_m$ the cracks propagate kinetically.

Degree of damage

When initially short cracks, $l_0 < l_m$, reach the region of instability, they propagate rapidly while the temperature changes just an infinitesimal. In order to determine the crack length after propagation, it is possible to assume that cracks extend until all the energy released is converted into crack surface energy. This is done by setting the difference between elastic energies for initial and final crack lengths equal to the difference between surfaces energies (Eq. (28)):

$$W_e(l_0) - W_e(l_f) = W_s(l_f) - W_s(l_0) \quad (28)$$

This allows the calculation of the final crack sizes, l_f , plotted in Fig. 5(b) with a dotted line.

Eq. (21) allows getting the value of the final size of short cracks after the kinetic propagation (Eq. (29)):

$$l_f = (4 \cdot \pi \cdot l_0)^{-1} \quad (29)$$

Applying the Griffith model, as above:

$$l_f \approx \frac{\sigma_f^2}{G \cdot E} \quad (30)$$

And for the tridimensional model, the final crack surface, S_f :

$$S_f \approx \frac{\sigma_f^2 \cdot (1 - \nu)}{G \cdot E} \quad (31)$$

Summary

In summary, the Hasselman model allows to obtain, from a single expression that encompasses the sum of elastic and surface energies (Eq. (19)), the following solutions:

- (1) Thermal condition for fracture onset, ΔT_c , that is, critical temperature difference for the propagation of short cracks. The parameter that maximizes ΔT_c (Eq. (25)) is the same as that obtained in the thermoelastic approach, R (Eq. (10)). The dimensional equation of this parameter is:

$$[R] = T \quad (32)$$

Therefore, its physical meaning is clear; the critical temperature difference is proportional to R .

- (2) Degree of kinetic propagation of short cracks. As shown in Eq. (31), the final size S_f is inversely proportional to the surface energy necessary for crack propagation, G , and directly proportional to the accumulated elastic energy (σ_f^2/E). In order to minimize S_f , it is necessary to maximize the same relationships between the properties of the material given by parameters R''' (Eq. (14)) and R'''' (Eq. (15)).

The dimensional equation of R'''' is:

$$[R'''''] = L \quad (33)$$

due to the fact that in the proportionality between the area through which the crack is spread and R'''' there is an effect of the microstructure of the material that is not included in this parameter:

$$S_f^{-1} = f(N, l_0) \cdot R'''' \quad (34)$$

- (3) The novelty of Hasselman's theory as compared to the thermoelastic theory and the energetic balance approach is that it allows explaining the behavior of long cracks ($l > l_m$). These cracks might be preexisting in the material or consequence of the kinetic propagation of short cracks. The parameter, R_{st} (Eq. (26)) maximizes the minimum temperature interval required to propagate long cracks, $\Delta T'_c$. However, simplification of Eq. (22) gives:

$$\Delta T'_c = f(N, l_0) \cdot R_{st} \quad (35)$$

Therefore, the parameter R_{st} also lacks of straightforward physical meaning, revealed by its dimensional equation:

$$[R_{st}] = T \cdot L^{\frac{1}{2}} \quad (36)$$

The conclusions of Hasselman's theory allow explaining the general behavior of materials subjected to thermal shock plotted in Fig. 3.

As discussed above for the thermoelastic approach, both parameters, R and R_{st} , will be modulated by the thermal conductivity of the material for mild conditions of heat transfer.

Selection of Materials

Before discussing the potential of the thermal shock resistance parameters for the selection of ceramics, it is important to remark a main result of the Unified Theory of Hasselman that is not included in the parameters. As described above, thermal shock fracture occurs in absence of external body forces. Therefore, the only energy available for crack propagation is the elastic energy accumulated in the body due to the constrained dimensional changes associated to the temperature change, ΔT . For ΔT_c , the cracks in the body propagate by transforming the elastic energy in surface energy until the former one is consumed. As the elastic energy is finite, the final crack length depends on the initial one and the density of cracks (Fig. 5), thus, ceramics with a large number of small defects degrade less than those with a small number of defects. This fact is currently applied for the development of thermal shock tolerant materials for applications such as kiln lining and furniture, thermal barrier coatings or crucibles for metal casting.

Characteristic values of the properties of materials involved in their response to thermal shock and the thermal shock resistance parameters associated are summarized in Tables 1–3. Structural ceramics suitable for high temperature applications are considered. The classical division between oxide and non-oxide technical ceramics and refractories is used for clarity. Simplified parameters not including the dependence on Poisson's ratio are considered.

Thermal expansion values are mainly determined by the phase composition of the materials, thus, values for oxide technical ceramics are similar to those of oxide refractories. Fused silica refractories present extremely low thermal expansion while MgO-graphite bricks have low thermal expansion as compared to magnesia bricks.

In general, technical ceramics present higher Young's modulus and strength than refractories while the latter have high fracture energies, especially the modern refractory castables with optimized microstructural design.

Non oxide ceramics are covalent bonded ceramics which results in high thermal conductivity and low values of thermal expansion, only mullite, cordierite and, especially, aluminum titanate, from the oxides present also low thermal expansion. The latter also has extremely low Young's modulus. The extremely low values of α and E for aluminum titanate materials are due to microcracking during cooling from the sintering temperature due to thermal expansion anisotropy, therefore, aluminum titanate materials present also very low strength. Zirconium titanate has also high thermal expansion anisotropy; therefore, zirconium titanate materials and its composites with zirconia also present some microcracking and associated low E.

In general, fracture of covalent materials is brittle because they cannot deform under stresses. Another characteristic related to the covalent bonding is the difficulty of sintering, which sometime requires additives, then, resulting properties are highly dependent on processing. In the case of Si₃N₄, optimization of processing can lead to a special microstructure made of β -Si₃N₄ tabular grains that present high resistance to crack propagation (self-reinforced Si₃N₄).

In Fig. 6 values of the thermal shock resistance parameters R and R_{st} (Tables 1–3) are plotted for the different materials.

In general, technical ceramics present much higher values of R (Fig. 6(a)) than refractories because they have higher strength, which make them materials appropriate for applications in which no cracking of the material is allowed, such as cutting tools for metal machining. Y-TZP is the oxide with most resistance to cracking by thermal shock because of its unique fracture behavior. In spite of its extremely low strength, aluminum titanate and fused silica refractories can be used in applications that require high thermal shock resistance, such as crucibles for metal cast, due to their low thermal expansion. The high thermal conductivity of non-oxides makes them as ideal materials for applications that involve high thermal shocks such as metal machining with lubricants, as revealed by the high values of R' (Table 1).

As revealed by the differences in the values of R''', 1–2 orders of magnitude higher for refractories (Table 3) than for technical ceramics (Tables 1 and 2), degradation of refractories once thermal shock fracture starts is less severe than that of the high strength technical ceramics. From these later, only cordierite presents especially high damage resistance, due to its low strength that leads to very low elastic energy available for cracking.

The parameter R_{st} that maximizes the resistance of materials to the propagation of long cracks, is similar to R'''' in that both parameters weight the relative effects of the fracture energy, G, and the elastic energy, represented by $\alpha^2 E$ in R_{st} (Eq. (26)) and σ_f^2/E in R'''' (Eq. (15)). The case of self-reinforced Si₃N₄ is special because it combines very high strength and fracture energy.

As discussed for R''', values of R_{st} plotted in Fig. 6(b) show how refractories, and especially the well-designed modern castables, are adequate for severe thermal shock conditions in which fracture initiation cannot be avoided. In fact, refractories are successfully used in all basic industries that involve thermal cycling at high temperatures: steelmaking, energy, cement, waste incineration, etc.

Final Remarks

The general aspects of thermal stresses and fracture have been discussed. A main straightforward conclusion is that the level of stresses created in a structure or component due to temperature changes is a function, not only of the thermal solicitations imposed, but also of the surface state, a number of material properties and geometrical factors. Therefore, the response to temperature variations is not an intrinsic property of the materials, such as the modulus of elasticity or the specific heat. It is not possible to think about one single experiment for characterizing the response of materials under all thermal solicitations.

The thermal shock parameters derived from classical works, that analyze the effect of the main material properties involved in the response to thermal shock and their relative influence, are useful to predict the relative performance of materials under specific temperature variations. Nevertheless, the effect of the microstructural factor, qualitatively analyzed by Hasselman in terms of the density of defects, should be quantitatively described in order to predict the actual behavior of the materials. Moreover, the simplifying assumption of calculating crack extension from the available elastic energy and a constant value of surface energy might not be valid for the new ceramics designed to develop toughening mechanisms during crack propagation.

Introduction

The thermal shock degradation of ceramic materials is commonly evaluated from quenching experiments, generally in water, and the measurement of the retained strength, σ_R (Baudin, 2020). σ_R remains constant until the applied temperature difference, ΔT , reaches a critical value, ΔT_c , and then decreases above this value. From Hasselman's classical approach (Hasselman, 1969, 1978), brittle materials are classified into two categories: low strength materials resistant to thermal shock damage for which the retained strength decreases gradually (Fig. 1(a)) and high strength materials resistant to crack initiation, for which it decreases instantaneously (Fig. 1(b)). Hence, the dilemma with ceramic materials is to design microstructures that exhibit both high strength and high thermal-shock damage resistance. More refined fracture mechanics approach in terms of stress intensity factor (SIF) or energy release rate (Evans and Charles, 1977; Swain, 1990; Pompe, 1993; Bahr *et al.*, 1993; Schneider, 1991) was developed, allowing to take into account the transient character of thermal shock and the toughness behavior of the material.

In this article, the mechanical approach will be presented and used to discuss the strength degradation of ceramic materials under thermal shock. A special focus will be put on the microstructural effects, in particular the possibility to obtain an optimal state between resistance to crack initiation and resistance to crack propagation under thermal shock (Fig. 1(c)), by increasing the crack growth resistance (R-curve behavior). The basic concepts of thermal fatigue will also be presented with examples of typical behaviors.

Fracture Mechanics of Thermal Shock

Due to the transient nature and the complexity of the thermal shock, associated crack propagation is difficult to capture with available experimental techniques. Numerical simulations and modeling are increasingly used (Schneider and Petzow, 1993; Schneider, 1991; Saâdaoui and Fantozzi, 1998; Collins and Rowcliffe, 2000; Li *et al.*, 2013) to determine thermal stresses and induced stress intensity factors in order to understand material response and predict crack initiation and crack growth under thermal shock conditions.

Transient Thermal Stresses

It is important to take into account the time dependence of induced stresses, which arises from the temperature gradient and the resulting strain differences between the surface and the bulk. Under thermal shock loading, the temperature field can be obtained from the equation of transient heat conduction:

$$\frac{\partial}{\partial x} \left(\lambda \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(\lambda \frac{\partial T}{\partial y} \right) + \frac{\partial}{\partial z} \left(\lambda \frac{\partial T}{\partial z} \right) = \rho C \frac{\partial T}{\partial t} \quad (1)$$

where t is time, ρ is the material density, C its specific heat and λ its thermal conductivity.

Fig. 1 Illustration of the strength degradation under thermal shock for (a) low-strength and (b) high-strength materials and (c) optimized microstructures.

Fig. 2 Illustration of an alumina sample (thickness 4 mm) submitted to thermal shock with a jet air at a critical applied temperature difference, $\Delta T_c = 845\text{K}$ (a) and the resulting transient normal stresses σ_{xx} at the median plane ($x = 0$) (b). From Saâdaoui, M., Fantozzi, G., 1998. Crack growth resistance under thermal shock loading of alumina. Materials Science and Engineering A247, 142–151.

In the case of quenching with a constant heat transfer coefficient h , the boundary condition at the surface of the body is:

$$\frac{\partial T}{\partial n} = \frac{h}{\lambda} (T_e - T_s) \quad (2)$$

where $\vec{n}$ is the outward normal of the surface, T_e is the temperature of the quenching medium and T_s the surface temperature. The thermal stress can be calculated as follows:

$$\sigma(y, t) = \frac{E\alpha}{1-\nu} (T(y, t) - T^*) \quad (3)$$

where E is the Young's modulus, α is the thermal expansion coefficient, ν the Poisson ratio and T^* is the temperature at the point where the thermal strain is zero.

An example of the time dependence of the thermal stresses is shown in Fig. 2 for rectangular alumina samples subjected to thermal shock by the application of two jets of pulsed air to the largest faces (Saâdaoui and Fantozzi, 1998). It can be seen that tensile stresses are generated in the surface region ($y = 0$) while the middle region ($y = 2$ mm) is subjected to compressive stresses. Figs. 2 and 3 show that the tensile stress at the surface increases rapidly up to about 1 s, then decreases after a maximum value. In this case, a peak of acoustic emission was observed when the maximum surface stress is reached and was correlated to the appearance of a large surface crack.

Crack Propagation Analysis

From the fracture mechanics point of view, the thermal shock strength degradation of ceramic materials is a consequence of the propagation of preexisting cracks or defects when subjected to sufficiently severe thermal shocks. For an extending surface crack with a length a , the applied thermal shock stress intensity factor, K_{TS} , can be determined at any time from the transitional thermal stresses using the weight function method (Pertroski and Achenbach, 1978; Tsai and Ma, 1992; Wu, 1993):

$$K_{TS}(a, t) = \int_0^a \sigma(x) h(x, a) dx \quad (4)$$

where x is the coordinate with the origin at the surface and $h(a, x)$ is the weight function independent of the stress.

The crack extension can be described by a diagram representing K_{TS} as a function of crack length, a , and time (Swain, 1990; Schneider, 1991), a schematic illustration of which is shown in Fig. 4, for an applied temperature difference larger than the critical value. As the thermal shock is a transient phenomena, K_{TS} increases with time for a given crack length, displays a peak value and then decreases. At a fixed time, K_{TS} passes through a maximum and all the curves have a common envelope which allows anticipating crack propagation modes and arrest, depending on the material behavior and thermal shock conditions.

Fig. 3 Variation with time of the tensile surface stress corresponding to conditions of Fig. 2. Apeak of acoustic emission was observed when the maximum surface stress is reached ($t = t_{AE}$).

Fig. 4 Illustration of crack growth under thermal shock loading for a material with a constant toughness, K_{IC} (curve 1) and a rising R-curve behavior (curve 2) where K_R is the crack growth resistance in terms of stress intensity factor.

A crack with an initial length a_i will extend following stable or unstable sequences depending on the toughness behavior. For a material with a constant toughness, K_{IC} , the crack propagation follows two stages (Fig. 4, curve (1)). The propagation is first unstable under the conditions:

$$K_{TS} = K_{IC} \quad (5a)$$

$$dK_{TS}/da > 0 \quad (5b)$$

then becomes stable with:

$$K_{TS} = K_{IC} \quad (6a)$$

$$dK_{TS}/da < 0 \quad (6b)$$

A crack arrest occurs with a final crack length, a_1 , determined by the envelope curve.

The crack propagation criterion can also be expressed by the energy release rate, G , using time-dependent G-curves (Bahr *et al.*, 1987). The different sequences of stable and unstable crack growth have been observed by Schneider *et al.* during model thermal loading experiments of ceramic disks by lamp irradiation (Schneider *et al.*, 1993). Their relative importance depend on material properties and thermal loading conditions, in particular the applied temperature difference (Schneider, 1991).

Ceramic materials with particular microstructures exhibit stress shielding effects due to reinforcement mechanisms as grain bridging (Steinbrech *et al.*, 1990; Vekinis *et al.*, 1990; Li *et al.*, 1992) or transformation toughening (Evans, 1990; Hannink *et al.*, 2000). Thus, their toughness increases with the crack length and the fracture behavior is described by a crack growth resistance curve (R-curve). In this case, the crack propagation under thermal shock is generally characterized by three consecutive stages (Fig. 4, curve (2)). The onset of crack propagation occurs when the applied thermal shock SIF, K_{TS} reaches the crack growth resistance, K_R :

$$K_{TS} = K_R \quad (7)$$

If the R-curve is steep enough, the crack extension is first stable as:

$$\frac{dK_{TS}}{da} < \frac{dK_R}{da} \quad (8)$$

and becomes unstable when:

$$\frac{dK_{TS}}{da} > \frac{dK_R}{da} \quad (9)$$

For large crack lengths, the extension becomes again stable as $dK_{TS}/da < 0$, thus the condition in Eq. (8) is always satisfied.

It can be seen that for the R curve material, the final crack length a_2 , is lower than that obtained with the constant toughness material (a_1), which leads to higher retained strength. Based on these theoretical considerations, an optimal state between resistance to crack initiation and resistance to crack propagation (Fig. 1(c)) is possible to obtain by increasing the crack growth resistance (R curve behavior). For quantitative analysis, suitable R curves under thermal shock conditions have to be considered as they are generally different from those determined under mechanical loading (Bahr *et al.*, 1993; Saâdaoui and Fantozzi, 1998).

It is to note that for ceramic materials, multiple cracking under thermal shock is usually observed experimentally (Gupta, 1972; Mignard *et al.*, 1995). Bahr *et al.* (1986) extended the above fracture mechanics approach to multiple cracking which was also simulated considering different models as in Jin and Fen (2009) and Li *et al.* (2013).

Microstructural Effects on Thermal Shock Resistance

On the basis of the fracture mechanical analysis, improvements in the resistance to thermal shock of ceramic materials can be obtained by tailoring their microstructures (Fantozzi and Saâdaoui, 2014) in order to improve their crack growth resistance (R-curve). For alumina, known to exhibit R curve behavior due to crack shielding by grain bridging, Steinbrech (1992) showed that the retained strength after thermal shock increases linearly with the slope of the R curve, due to the increase of the shielding effect with the grain size. For Si_3N_4 ceramics, it has been shown that the thermal shock resistance can be enhanced by coarsening and elongating the microstructure, via the influence on toughness and R-curve behavior (Hoffmann *et al.*, 1993; Lee *et al.*, 2002). Controlled grain coarsening, inducing a high crack growth resistance, allows maintaining a high initial strength, which decreases gradually after thermal shock, compared to the typical catastrophic strength loss observed in a fine grain material (Fig. 5).

Improvement in thermal shock resistance over a single phase ceramic material can be achieved by the incorporation of a second phase particles as for ZrO_2 reinforced Al_2O_3 , (Becher, 1981; Swain, 1990), SiC reinforced Si_3N_4 (Kovalcikova *et al.*, 2009), and BN reinforced Si_3N_4 (Lutz and Swain, 1992). For example, Becher (1981) showed that incorporating zirconia particles in alumina increases the critical temperature difference and allows to obtain materials with high initial strength, which exhibit only moderate degradation after thermal shock. This can be attributed to the non-linear stress-strain and R-curve behavior of these composites as suggested by Swain (1990). Lutz *et al.* (1991) have shown that the thermal shock behavior of high strength alumina-zirconia composites can be significantly modified by incorporating pressure zones in a duplex structure that induces crack growth resistance. The authors used a power function ($K_R \propto a^\tau$ the logarithmic slope of which is an indication of the importance of the R curve behavior): $\tau = 0$ corresponds to constant toughness and $\tau > 0$ indicates pronounced R curve behavior the intensity of which increases with τ . Fig. 6 shows that the thermal shock strength degradation is significantly decreased for the duplex ceramics with pronounced R curve behavior.

Ceramic materials with pronounced R-curve behavior and minimal thermal shock degradation often exhibit nonlinear stress-strain behavior attributed to stress induced microcracking or transformation toughening in ZrO_2 containing ceramics (Lutz, 1993;

Fig. 5 Thermal shock behavior of Si_3N_4 ceramics: (1) fine grain size and (2) optimally coarsened microstructure. From Hoffmann, M.J., Schneider, G.A., Petzow, G., 1993. The potential of Si_3N_4 for thermal shock applications. In: Schneider, G.A., Petzow, G. (Eds.), Thermal Shock and Thermal Fatigue Behaviour of Advanced Ceramics. Dordrecht: Kluwer Academic Publishers, pp. 49–58.

Fig. 6 Relative retained strength for duplex alumina-zirconia duplex composites as a function of the amplitude of the R curve: $\tau = 0$ corresponds to a material with a constant toughness (flat R curve) and $\tau > 0$ corresponds to R curve effect the intensity of which increases with τ . From Lutz, E.H., Swain, M.V., Claussen, N., 1991. Thermal shock behaviour of duplex ceramics. *Journal of the American Ceramic Society* 74, 19–24.

Swain, 1990). During the nonlinear deformation, the Young's modulus of a material decreases according to the expression (Gogotsi *et al.*, 1978):

$$E(\varepsilon) = E_0[1 - \omega(\varepsilon)] \quad (10)$$

where $\omega(\varepsilon)$ is an increasing function with strain.

This induces a reduction of the elastic modulus of the material and hence, a reduction of the elastic energy available for crack propagation under thermal shock.

Other reinforcement strategies that allow to enhance the thermal shock resistance, compared to monolithic ceramics, include whiskers reinforcement (Tiegs and Becher, 1987), ductile reinforcement (Aldridge and Yeomans, 1998; Jin and Batra, 1999) and fiber reinforcement (Wang and Singh, 1994; Singh and Wang, 1995). Excellent thermal shock resistance can be reached due to crack bridging by the reinforcing phase that increases the crack growth resistance and prevents coalescence of the cracks present in the matrix into critical flaws.

The concept of functional grading or multilayered architectural design of ceramic materials has attracted considerable interest, as ceramic composites with layered structure may exhibit high work of fracture and non-catastrophic failure behavior (Lugovy *et al.*, 2005; Bermejo *et al.*, 2006, 2008). High thermal shock resistance can be reached in these materials due to the formation of surface compressive residual stresses, as reported for alumina-zirconia (Bermejo *et al.*, 2005) and $\text{ZrB}_2\text{-SiC}$ (Zhou *et al.*, 2016) laminate composites and a Sialon- Si_3N_4 graded composite (Zheng *et al.*, 2012). These compressive stresses shield the crack tip from the applied thermal stresses during thermal shock and thus decrease the driving force for crack propagation. Moreover, Vandeperre *et al.* (2011) showed that the presence of deflecting weak interlayers enhanced the thermal shock resistance of alumina-zirconia laminate composites, as they increase the resistance to the penetration of a crack under thermal shock loading, compared to laminates in which cracks are not deflected for monolithic ceramics.

Thermal Fatigue

Thermal fatigue i.e., fatigue caused by a thermally induced stress is an important phenomenon that can limit the lifetime of ceramic components. Conversely to thermal shock, thermal fatigue has not been intensively studied. An important problem is the result scattering that asks to realize a large number of experiments. Moreover, the precise stress field is difficult to evaluate because of the transient nature and the number of involved parameters.

Fundamental Aspects

Thermal fatigue experiments are generally conducted by heating a specimen and subsequently quenching it in water or air. The damage is evaluated by measuring a characteristic property of the material, as the elastic modulus or the mechanical strength, after successive thermal shock cycles. The measurement of the elastic modulus is a non-destructive test that allows to rely its decrease to the nucleation and the propagation of cracks in the ceramic. Furthermore, the elastic modulus is sensitive to the entire ensemble of cracks whereas the measurement of mechanical strength is rather sensitive to the largest crack and is a destructive test (Case *et al.*, 1993).

Fig. 7 Evolution of the elastic modulus as a function of the number of quenching tests for $\Delta T = 1000^\circ\text{C}$ for a zircon-mullite composite. From Rendtorff, N.M., Garrido, L.B., Aglietti, E.F., 2011. Thermal shock resistance and fatigue of zircon-mullite composite materials. *Ceramics International* 37, 1427–1434.

An example of the evolution of the elastic modulus during thermal fatigue for a zircon-mullite composite is shown in **Fig. 7** (Rendtorff *et al.*, 2011). The thermal fatigue induced modulus decrease can be described by the following empirical equation:

$$E/E_0 = B + (1 - B) \exp(-bN) \quad (11)$$

where E is the elastic modulus after N thermal cycles at a fixed ΔT (quench temperature difference), E_0 is the elastic modulus before quenching in water (microcrack free material), B is a saturation parameter and b is a rate parameter.

The parameter B corresponds to the steady state value of the elastic modulus obtained after a certain number of thermal cycles and b corresponds to the rate at which the thermally fatigued specimen reaches saturation. A higher B and a lower b represent better thermal fatigue behaviors.

Similar evolution is also obtained for the mechanical strength or the internal friction of thermally fatigued ceramics (Case *et al.*, 1993; Lee and Case, 1989). Internal friction is more sensitive to the microcrack damage than elastic modulus due to the rubbing of opposing crack faces leading to frictional energy dissipation.

Moreover, the thermal fatigue behavior of a brittle material can be investigated by measuring the critical number of thermal shock cycles (lifetime), N_c , required to provoke the failure of specimens submitted to a thermal fatigue with a temperature difference, ΔT . Kamiya and Kamigaito (1976) have made a prediction of the thermal fatigue life by application of fracture mechanics based on subcritical crack growth under thermally induced stresses. The crack growth rate da/dt can be described by the following power law:

$$da/dt = AK_I^n \quad (12)$$

where a is the crack length, K_I is the stress intensity factor, A and n are material constants which depend on the environment. K_I can be expressed as:

$$K_I = \sigma_{th} Y a^{1/2} \quad (13)$$

where σ_{th} is the stress characteristic of the thermal shock (generally the maximum stress on the specimen surface), Y is a configuration coefficient dependent on the crack and sample shapes.

The thermal stress, σ_{th} , is a function of time and temperature difference and can be expressed by the following relation:

$$\sigma_{th} = \Delta T f(t) \quad (14)$$

where $f(t)$ is a function of time.

By combining Eq. (14) with Eqs. (12) and (13), the differential Eq. (12) describing the crack propagation becomes:

$$da/dt = A \Delta T^n f^n(t) Y^n a^{n/2} \quad (15)$$

Assuming that Y is independent of a , the integration of Eq. (15) over the total crack propagation (assuming $a_f^{-n} \ll a_i^{-n}$ with a_i and a_f corresponding respectively to the initial and the final crack lengths) allows to determine the lifetime of the ceramic, N_c :

$$(a_i)^{\frac{2-n}{2}} = \frac{n-2}{2} N_c A \Delta T^n Y^n \int_0^{t_c} f^n(t) dt \quad (16)$$

where t_c is the cycle duration.

Generally, the crack growth parameter n can be determined for ceramics having the same initial crack length a_i from the measurement of N_c for a series of applied temperature differences ΔT (from Eq. (16)):

$$N_c/N'_c = (\Delta T'/\Delta T)^n \quad (17)$$

where N'_c is the critical number of thermal cycles corresponding to a temperature difference $\Delta T'$.

Fig. 8 (a) Survival probability, P , versus thermal fatigue life N_c , (b) N_c versus ΔT for yttria-stabilized zirconia. From Kamiya, N., Kamigaito, O., 1976. Prediction of thermal fatigue life of ceramics. *Journal of Materials Science* 14, 573–582.

However, ceramics exhibit different initial crack lengths and the Eq. (17) must be applied for the median or mean values of the critical number of thermal cycles (or for a common survival probability) as suggested by Kamiya and Kamigaito (1976). An example of such analysis applied to yttria-stabilized zirconia is given by Fig. 8. The survival probability, P , under the thermal shock cycle is given by Weibull statistics and the plot of $\ln(-\ln P)$ versus the thermal fatigue life, N_c , gives a straight line for a given value of ΔT , the slope of which is equal to m/n , where m is the Weibull modulus. The n value can be determined according to Eq. (17) by plotting $\ln N$ versus $\ln(\Delta T)$ for a given value of survival probability (Fig. 8(b)). The determined m value is about 15 and the n value is about 20.

The plot of $\log N_c$ versus $\log a_i$ can be fitted by a straight line (Eq. (16)) with a slope equal to $2/(n-2)$. The A parameter can be determined from the evolution of the thermal stress σ_{th} and the configuration coefficient Y . For example, this analysis was applied to an homogeneous alumina ceramic with a fine grain size of 3 μm (Saadaoui *et al.*, 1999). The thermal fatigue experiments were carried out by using bars with controlled indentation flaws. The indented samples were heated and cooled (with a temperature difference of 830°C) by two jets of pulsed air as shown in Fig. 2(a). The critical thermal cycle number, N_c , determined by acoustic emission is plotted as a function of the initial crack length, a_i , in Fig. 9. There is a significant scattering but a decrease of N_c with increasing crack length is observed. Above a limit value of a_i ($= 120 \mu\text{m}$), unstable crack growth occurs during the first cycle (when the fracture toughness K_{IC} is reached). The plot of $\log N_c$ versus $\log a_i$ can be fitted by a straight line with a slope equal to $2/(n-2)$, from which a value of $n = 18$ was obtained.

Fig. 9 Critical number of thermal cycles versus the initial crack length. From Saâdaoui, M., Olagnon, C., Fantozzi, G., 1999. Thermal fatigue of alumina: Comparison with mechanical data and life time prediction. *Ceramics International* 25, 497–504.

Fig. 10 Thermal fatigue domain compared to the subcritical crack growth laws obtained under mechanical loading: Double torsion at 20°C (curve 1); Double torsion at 800°C (curve 2); Dynamic fatigue at 800°C (curve 3); Double torsion at 20°C, cyclic loading (curve 4). From Saâdaoui, M., Olagnon, C., Fantozzi, G., 1999. Thermal fatigue of alumina: Comparison with mechanical data and life time prediction. *Ceramics International* 25, 497–504.

The A parameter is determined from the knowledge of the thermal stress and the configuration coefficient Y is calculated by finite element. Thus the crack growth rate under thermal loading is obtained (Fig. 10). The crack growth rates under mechanical loading (measured by double torsion and dynamic fatigue methods) are equally shown.

The crack growth rate under thermal loading is higher than under static isothermal loading in a large domain of stress intensity factor and it is close to that observed under mechanical cyclic loading. Thus, the lifetime prediction under thermal fatigue cannot be deduced from the slow crack growth obtained from monotonic mechanical loading as for glass (Fett *et al.*, 1991). Cyclic fatigue effects as well as temperature variation must be taken into account. The physical mechanisms intervening during the thermal loading need to be specified and the R-curve effect should be taken in consideration.

Microstructural Effects

In order to increase the thermal fatigue resistance of ceramics, different reinforcement mechanisms can be used improving the mechanical strength, toughness and thermal shock parameters (Fantozzi and Saâdaoui, 2014). This is illustrated by some examples which will be developed below.

Rendtorff *et al.* (2011) have studied the thermal fatigue behavior of zircon-mullite composites with different compositions and dense microstructures as shown in Fig. 11. Two composites denoted ZM15 and ZM45 contain respectively 82 and 46 wt% of zircon (middle gray), 14 and 44 wt% of mullite (dark gray), and 4 and 10 wt% of zirconia (white). Increasing the fracture toughness K_{IC} from 2.04 (for ZM15) to 2.72 MPa m^{1/2} (for ZM45) increases the thermal shock parameter R_{st} from 1.43 (for ZM15) to 2.72 (for ZM45).

It was shown that a clear correlation is obtained between the B parameter (Eq. (11)) and the thermal shock parameter, R_{st} (Fig. 12) which characterizes the behavior of ceramics with long cracks under severe thermal stresses (Baudin, 2020):

$$R_{st} = \left(\frac{G}{\alpha^2 E} \right)^{\frac{1}{2}} = \frac{K_{IC}}{(2\alpha E)^{\frac{1}{2}}} \quad (18)$$

where, G is the fracture surface energy, α is the linear thermal expansion coefficient and K_{IC} is the fracture toughness.

The same correlation has been observed by Tian *et al.* (2008) for Si_3N_4 -TiC nano-composites. The microstructures of monolithic Si_3N_4 and Si_3N_4 -TiC nano-composites consist of spherical grains (~ 100 nm) reinforced with TiC particles for the composite ($\sim$ less than 1 μm). The crack growth versus the number of thermal cycles of water-quenched samples with a temperature difference $\Delta T = 600^\circ C$ is shown in Fig. 13 for the monolithic ceramic and for a nano-composite containing 10 wt% TiC. The crack propagation of the nano-composite is clearly lower than the monolithic one. This is linked to the strengthening and to the toughening of the nano-composite, due to the crack-tip bridging and to the crack deflection by the TiC particles as shown by Fig. 14. The fracture toughness is an important factor to evaluate the thermal shock resistance of ceramics as shown by the preceding examples and an appropriate microstructure allows to optimize the thermal shock and thermal fatigue resistance.

The thermal fatigue behavior of oxide/oxide ceramic matrix composites has been recently studied by Yang *et al.* (2019) by following the evolution of the elastic modulus. The composite consists of $0^\circ/90^\circ$ woven Nextel 610 fibers (99% α -alumina) in an alumina (85 wt%)- 3YSZ (15 wt%) porous matrix. Fig. 15 shows the decrease of the elastic modulus as a function of the number of cycles for different applied thermal shock temperatures (the thermal shock test was performed by heating the specimen up to the thermal shock temperature and quenching in water) and for two directions: 0° (warp bundles) and 90° (weft bundles). This decrease of elastic modulus is due to nucleation and propagation of micro-cracks in the matrix, the fibers being not damaged.

Thermal shock and thermal fatigue resistance of Sialon- Si_3N_4 graded composite ceramic materials have been studied by Zheng *et al.* (2012). Thermal fatigue tests were performed by using an indentation-quench method. Five Vickers indents were introduced on the wide surfaces of the polished samples with dimensions of 3 mm x 4 mm x 35 mm. The indented samples were heated in a high temperature furnace for 20 min and then dropped into $20^\circ C$ water. The length of cracks (defined as the distance from the center of the indent to the crack tip) was measured after thermal shock. The Sialon- Si_3N_4 graded composite fabricated by hot pressing were made of five-layered graded materials with symmetrical structure. The first layer (ST10) of the composite named

Fig. 13 Crack growth as a function of the number of thermal cycles for a temperature difference $\Delta T = 600^\circ\text{C}$ for a monolithic Si_3N_4 ceramic (1) and a nano-composite with 10 wt% TiC (2). From Tian, C., Liu, N., Lu, M., 2008. Thermal shock and thermal fatigue behavior of Si_3N_4 -TiC nano-composites. *International Journal of Refractory Metals and Hard Materials* 26, 478–484.

Fig. 14 Propagation path of crack after thermal shock for a monolithic ceramic (a) and a nano-composite (b). From Tian, C., Liu, N., Lu, M., 2008. GSS1 is constituted of the major phases $\beta\text{-Si}_3\text{N}_4$ and $\text{TiC}_{0.7}\text{N}_{0.3}$ whereas the first layer (SAAT10) of the composite named GSS2 corresponds to the β -Sialon phase. The second and third layers of the composites are the same.

Several toughening mechanisms intervene for the surface layer of the composites such as reinforcement by intergranular and transgranular TiCN particles, crack deflection and twin structure. The TiCN particles deflect the crack to travel through a tortuous path and participate to an increase of the fracture energy. Therefore, the graded ceramic composites exhibit higher mechanical properties: the flexural strength σ_f is 980 MPa (for the GSS1 composite) and 810 MPa (for the GSS2 composite) and the fracture toughness of the surface layer is 9.54 and 9.33 $\text{MPa m}^{1/2}$ respectively. Fig. 16 shows the crack extension as a function of the number of cycles for a thermal shock $\Delta T = 400^\circ\text{C}$ for the composites and the homogeneous ceramics. The crack growth in

the graded ceramic composites is much lower than in the homogeneous ceramics. Thus, the thermal fatigue resistance of the graded ceramic composites is higher than the homogeneous ceramic one. This increase may be linked to the increase of flexural strength and fracture toughness of the surface layer compared to the homogeneous ceramic. Furthermore, compressive residual stresses appear at the surface layer of the graded composites due to the difference of the thermal expansion coefficient which is higher at the center compared to the surface. These compressive stresses counteract the tensile stresses generated during the thermal shock.

Phenomenological Aspects

At high temperatures, under a constant stress, plastic deformation called creep occurs and the creep strain as a function of time depends on the applied stress σ and on the temperature T . Typical creep curves can be generally reported into three stages as shown in **Fig. 1**:

- A primary stage where the creep rate decreases with time.
- A secondary stage called steady-state stage where the creep rate is almost constant.
- A tertiary stage where the creep rate increases strongly up to the failure (formation of cracks or voids).

These three stages are not independent because creep is a continuous phenomenon. Under low applied stress, the third stage can disappear and under high stress, the secondary stage can be replaced by an inflexion point. Usually, only the steady-state stage is considered. This steady-state stage is not always observed and very often the minimum creep rate is taken into account to study the creep behavior of ceramics.

Most creep models predict a dependence of creep rate on the temperature, stress and microstructure according to the general Norton relationship:

$$\dot{\epsilon} = \frac{AD}{kT} \frac{\sigma^n}{d^m} \quad (1)$$

A = material constant (which depends on the creep mechanism, see Section "Creep Mechanisms")

D = diffusion coefficient = $D_0 \exp(-Q/RT)$, D_0 = constant, R = gas constant, Q = activation energy, T = absolute temperature.

k = Boltzman's constant.

d = grain size.

σ = applied stress.

m and n = grain size and stress exponents, respectively.

m , n , and Q depend on the creep mechanism pertaining during creep.

Theoretically, the creep mechanisms can be identified by determining the exponents m and n . But very often, two (or more) creep mechanisms can occur simultaneously or sequentially and a complete analysis of the strain-stress relation cannot be analyzed by using a single exponent value.

The dominant creep mechanisms controlling the creep behavior depend on structures, microstructures, and stress regimes.

Of particular importance are the mode of loading and the testing method used for the creep characterization. Tensile tests are the most relevant test type for a homogeneous stress but are difficult and expensive to conduct. Alternatively, compressive tests are often conducted because they utilize a simpler load application system. Bending tests are also easy to conduct, are inexpensive and are very often used although the stress state is not homogeneous.

Creep Mechanisms

At sufficiently high temperatures, (above half of the melting point), the creep of materials can be governed by several mechanisms: the non-conservative motion of dislocations (recovery creep), the pure transport of matter (diffusional creep), or by grain boundary sliding accommodated by transport of matter.

Recovery Creep

For the non-conservative motion of dislocations, the different mechanisms describing recovery creep are derived from the Orowan equation:

$$\dot{\epsilon} = \rho_m b v_m \quad (2)$$

where ρ_m is the density of mobile dislocations, b is the Burgers vector and v_m is the velocity of dislocations that is controlled by climb and given by σD , see **Table 1** which shows the different models derived from microscopic observation (**Poirier, 1976**).

In 1957, Harper-Dorn observed that in materials with saturation of dislocations, ρ_m is constant and $\dot{\epsilon} \sim \sigma D$. If the deformation is due to pure climb (Nabarro model), $\dot{\epsilon} \propto D \sigma^3$. In the rest of models the deformation is due to the glide of dislocation and the strain rate is controlled by the climb as illustrated by the Weertman model depicted in **Fig. 2**.

Fig. 1 Typical creep curves at constant stress: (a) two stages (1) and (2) at low temperature or low stress, (b) three creep stages (1 – 3), (c) at high temperature or high stress. From Fantozzi, G., Chevalier, J., Olagnon, C., Chermant, J.L., 2000. Creep of ceramic matrix composites. Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), *Comprehensive Composite Materials*, vol. 4. Oxford: Elsevier.

Table 1 Different recovery creep models

ρ_m	L	d	v_m		$\dot{\epsilon}$	Model
$\frac{ML^2}{d}$	$(Md)^{-1/2}$	σ^{-1}	σD	$M = \text{cte}$	$D\sigma^{4.5}$	Weertman 1968
L^{-2}	σ^{-1}	L	σD		$D\sigma^3$	Nabarro 1967
$\frac{ML^2}{d}$	$(Md)^{-1/2}$	σ^{-1}	σD	$M = \frac{\rho_m}{d}$	$D\sigma^3$	Weertman 1972
$\frac{a\sigma^2}{L}$		σ^{-1}	σD	$a = \text{cte}$	$D\sigma^4$	Blum 1971
$\frac{N}{HL}$	$\sigma^{-2/3}$	$\frac{H}{N}$	$N\sigma D$	$H \propto \sigma^{-1}$ $H \propto \sigma L$	$D\sigma^3$ $D\sigma^4$	Weertman 1972
Cte			σD		$D\sigma$	Harper-Dorn 1957

Note: In the table, L is the size of the dislocation network, M is the density of Frank–Read sources, d is the climb distance, a is the width of dislocations, N is the number of dislocations pile-up, and H is the mean distance of dislocations in the pile-up.

Fig. 2 The Weertman creep model for recovery creep.

The backstress due to the dislocation pile-up on the sources S and S' cancel the external applied stress and the sources cannot emit any more dislocations; the dislocations at the head of the pile-up recombine by climb, the backstress decreases and the sources can emit new dislocations. Thus, the strain (ϵ) is produced by the glide of the new dislocations and the strain rate ($\dot{\epsilon}$) is controlled by the dislocation climb at the point of pile-up.

In general:

$$\dot{\epsilon} \propto \sigma^n D \quad (3)$$

with $n \geq 3$. This picture gives rise to the so-called natural power law model and it is always possible to find an ad-hoc model to adjust the stress exponent to the experimental values.

For a compound (monolithic ceramic) $A_\alpha B_\beta$, D is given by the molecular diffusion coefficient D_{mol} (Philibert, 1982).

$$D_{\text{mol}} = \frac{D_A D_B}{\alpha D_B + \beta D_A} \quad (4)$$

D_A and D_B can be expressed by the corresponding expression:

$$D_A^{eff} = D_A^l + 10 \left(\frac{\sigma}{\mu} \right)^2 D_A^p + \frac{\pi \delta}{d} D_A^{Gb} \quad (5)$$

In this expression, l is lattice, p is pipe diffusion, Gb is grain boundary, δ is the grain boundary thickness and the superscript indicates the path for diffusion, the prefactor of D_x^p and D_x^{Gb} are taken as $10 \left(\frac{\sigma}{\mu} \right)^2$ and $\frac{\pi \delta}{d}$ respectively (Ashby and Frost, 1975). The same treatment can be applied for the species B.

From Eqs. (3) and (4), it can be concluded that the rate-controlling process for creep is the motion of the slowest diffusing species along the easiest path.

Diffusional Creep

Regarding diffusional creep, the deformation is due to pure transport of matter and it is generally produced at high temperature $T \geq \frac{T_M}{2}$ (T_M is the melting temperature) and low non-isostatic stress field. According to the ideas of Nabarro (1948) and modified by Herring (1950), the equilibrium concentrations of vacancies differ, depending of the orientation of the surfaces or interfaces where they can be generated or annihilated. The difference in vacancy concentration produces a flux proportional to the gradient of chemical potential which gives rise to a mass flow. The transport can take place in the lattice (Nabarro–Herring) or along the grain boundary (Coble). As previously explained, for a compound A_xB_y , the molecular diffusion coefficient D_{mol} is written as in Eq. (4), and D_A^{eff} will be given by Eq. (6):

$$D_A^{eff} = D_A^l + \frac{\pi \delta}{d} D_A^{Gb} \quad (6)$$

and similar treatment applies to B.

The gradient of chemical potential is of the order of $\sigma \Omega / L$ (Ω is the atomic volume and L is the mean grain size) and then the mass flux $J \propto D^l \sigma / kTL$ and the number of atoms transported per unit of time and per face (L^2) is $\Phi \approx JL^2$ producing a volume change per face and unit time of $\Delta V = J\Omega L^2$ distributed over L^2 or a change in length $J\Omega$ per unit time and so a strain rate:

$$\dot{\epsilon} = \frac{1}{L} \frac{dL}{dt} = \frac{1}{L} J\Omega \quad (7)$$

In the following L is replaced by d (grain size). When the flux of vacancies is along the bulk, the strain rate is written:

$$\dot{\epsilon} = B \frac{D^l \sigma \Omega}{kT d^2} \quad (8)$$

In 1963, Coble considers that the mass flow can occurs along the grain boundary and then the strain rate will be:

$$\dot{\epsilon} = C \frac{\sigma \Omega D^{Gb} \delta}{d^3 kT} \quad (9)$$

The constants B and C depend on the grain shape factor and the applied stress system and in general $B \approx 13$ and $C \approx 24$. For details see Philibert (1982).

In general the viscous flow can comprise of both volume and grain boundary mass flow can contribute to the mass transport and then the strain rate is:

$$\dot{\epsilon} = A \frac{\sigma \Omega}{d^2 kT} \left(D^l + \frac{\pi \delta D^{Gb}}{d} \right) \quad (10)$$

with A being a dimensionless constant.

Assuming a grain boundary thickness (δ) of 1 nm, the term $\frac{\pi \delta}{d}$ in Eq. (10) can vary by several orders of magnitude depending on the grain size. Therefore, depending on the activation energies of the diffusion coefficients, D^l can be smaller than D^{Gb} multiplied by the term $\frac{\pi \delta}{d}$ and, consequently, diffusion through the lattice will be rate controlling. However, when the grain size decreases, this inequality can change, and the grain boundary diffusion can be rate controlling. This can be summarized from the Fig. 3 (Dominguez-Rodriguez *et al.*, 2010).

As it can be observed in the figure, the dashed lines (3) and (4) stand for the effective grain boundary diffusion coefficient $\frac{\pi \delta}{d} D^{Gb}$ for nanometric (30 nm) and micrometric (1 μ m) grain sizes, respectively. T_1 and T_2 correspond to the transition temperature for lattice to grain boundary diffusion for the two ranges of grain size. Below T_2 diffusion along grain boundary controls plasticity, although no plasticity is expected under these conditions. In nanometric specimens, such a transition can occur below T_1 , when grain boundary diffusion can be expected.

Grain Boundary Sliding

In diffusional creep in order to maintain cohesion between the grains, grain boundary sliding (GBS) occurs as shown in Fig. 4. This type of GBS is termed as "Lifshitz" GBS.

A different picture arises when GBS is responsible for the deformation, as shown in Fig. 5.

Fig. 3 Schematic plots of the diffusion coefficients versus inverse of temperature. The solid lines 1 and 2 correspond to a hypothetical grain boundary D^{gb} , and lattice diffusion coefficient D^l respectively. The dashed lines correspond to D^{gb} at 30 nm and 1 μm grain sizes, respectively. From Dominguez-Rodriguez, A., Gomez-Garcia, D., Castillo-Rodriguez, M., Zapata, E., Chaim, R., 2010. Superplasticity in nanoceramics: Achievements and open questions. *International Journal of Materials Research* 101, 1215–1221.

Fig. 4 Schema of the Lifshitz GBS. The thick line shows the GBS after deformation.

Fig. 5 Schema of the Rachinger GBS showing that the grain shape remains constant after deformation. From Ashby, M.F., Verrall, R.A., 1973. Diffusion-accommodated flow and superplasticity. *Acta Metallurgica* 21, 149–163.

In order to release stresses created during GBS, deformation is to be accompanied by intergranular slip throughout adjacent grains, by localized slip adjacent to the boundaries or by diffusional processes involving point defect migration. Sometimes, formation of triple point follows and the opening-up of cracks at the triple points can also accommodate GBS; however, as soon as there is coalescence of voids or cracks, the material fails and that happens at not so-large deformations. This type of GBS, accommodated by the process described above, is termed as 'Rachinger grain boundary sliding'. When this occurs, the average grain size and shape remain unchanged after large deformation values being the main feature of this regime.

Fig. 6 Experimental temperature-compensated strain rates vs stress plots for compressive creep of silicon nitride-based ceramics. The stress exponent $n = 1$ is shown for comparison. Creep of Monolithic Ceramics and Deformation Maps

Creep of Monolithic Ceramics

Ceramics can be classified into oxide ceramics and non-oxide ceramics. In the first class, Al_2O_3 has been studied more extensively than any other ceramics. In the case of non-oxide ceramics, SiC and Si_3N_4 are the most extensively studied.

Al_2O_3 is a stoichiometric ceramic and small amount of impurities can dramatically change the mechanical behavior. At high temperatures, the creep equation is a function of the diffusion coefficients of the species controlling the plasticity and it has been shown (Heuer, 2008) that there is a very high scatter in these values and as a consequence, of the creep parameters. The creep rate depends on the grain size, the purity and the composition of the glassy phase eventually present in grain boundaries. The values obtained experimentally for m , n , and Q are $0 < m < 3$, $0.7 < n < 3.3$ and $295 < Q < 840 \text{ kJ mol}^{-1}$ (Chevalier *et al.*, 1997). A large number of mechanisms can correspond to the obtained values for m and n exponents. Furthermore, two or more mechanisms can occur simultaneously. For alumina, the possible mechanisms are the following: lattice mechanism (dislocation creep), diffusion creep (Nabarro–Herring and Coble creep), grain boundary sliding, cavitation creep and microcracking. Some data concerning creep of alumina will be presented in Figs. 15, 16, and 18.

For non-oxide ceramics, a review article (Melendez-Martinez and Dominguez-Rodriguez, 2004) showed creep data for Si_3N_4 . In this ceramic, the creep data depend on whether the ceramic is deformed under compression or under tension. In order to avoid confusion, only the values under compression are represented (Fig. 6). The references shown in Fig. 6 can be obtained in the article (Melendez-Martinez and Dominguez-Rodriguez, 2004).

Silicon nitride ceramics are a very complex system with generally more than one phase. No model accounts for the experimental results with a complete success and it is difficult to determine the creep mechanisms. Creep is due to a series of mechanisms occurring simultaneously. Compression creep occurs by grain boundary sliding, accommodated by solution-precipitation. Tensile creep is influenced by cavitation. The presence of secondary glassy phases differently influences the creep behavior under compression and under tension.

Deformation Maps

It is useful to have a procedure to summarize, at a glance, for a given polycrystalline material, information about the range of dominance of the mechanisms controlling plasticity. A good review of deformation maps can be found in the book from Frost and Ashby (1982).

In order to construct a map, it is necessary to perform creep tests for a well-defined ceramic. However, the maps are critically dependent on the microstructure of the specimen under study. This fact implies that a same material can exhibit quite different maps as a function of differences in their microstructures. A good example is shown when compared the deformation maps in NiO

Fig. 7 Deformation map for NiO with grain size of 70 μm . From Krishnamachari, V., Notis, M.R., 1977. High temperature deformation of polycrystalline NiO and CoO. *Acta Metallurgica* 25, 1307–1313.

for grain size of 70 μm (**Fig. 7**) (Krishnamachari and Notis, 1977) and for NiO with grain size of 9 μm (Jimenez-Melendo *et al.*, 1986) (**Fig. 8**). In the latter map, there are three data sets (a, b, and c) corresponding to the creep data for different authors as explained in Jimenez-Melendo *et al.* (1986).

Superplasticity

Superplasticity is macroscopically defined as the ability of a polycrystalline material to exhibit large elongations at elevated temperatures and relatively low stresses. This is commonly found in a wide range of materials from metals to ceramics when the grain size is small enough: a few micrometers in the case of metals and less than a micron for ceramics. The first observation of superplasticity was reported in a 3 mol% yttria-stabilized tetragonal zirconia polycrystal ceramic (Y-TZP) with a grain size of 0.4 μm and deformed at 1450°C and $3 \times 10^{-4} \text{ s}^{-1}$ (Wakai *et al.*, 1986) (**Fig. 9**).

On a microscopic scale, a superplastically deformed polycrystal is characterized by its microstructure, i.e., grain size and form factor, almost unchanged after deformation, and it is generally accepted that these features are mainly achieved through grain boundary sliding. Clear evidence of grain boundary sliding during ceramic superplasticity can be observed in **Fig. 10**, which shows the relative motion of grains during deformation of Y-TZP (Duclos, 2004). It can be observed how two small grains, initially separated by two larger grains in contact, become nearer and nearer and finally the larger grains are separated. Several examples of switching events are also shown in the same reference (Duclos, 2004). As shown in **Fig. 10**, superplasticity occurs not only in tension, even though the polycrystal is deformed in compression, or in three- or four-point bending conditions, as long as GBS is the primary process (Dominguez-Rodriguez *et al.*, 2006).

Since the structure and the nature of the grain boundaries can be profoundly modified by segregation or glassy phases, the accommodation processes which control the strain rate of superplasticity are also affected by segregation and second phases. In the case of segregation, several important factors can be recognized: the ionic radius of the impurities, their charge, the binding energy between the host atoms and the impurities. In the case of secondary phase, it may act as a “lubricant” so that the viscous movement of the glassy phases constitutes an accommodation mechanism for grain boundary sliding.

As it was already explained, cavitation can be discarded as an accommodation mechanism for superplasticity, since the strain-to-failure afforded by this mechanism is rather small. Another important point is concerned with the activation of dislocations; as indicated in Castaing *et al.* (1989) and Dominguez-Rodriguez *et al.* (2013). For zirconia, the stresses needed to activate dislocations in cubic zirconia single crystals (170–300 MPa), as well as in tetragonal yttria stabilized zirconia single crystals (400 MPa) when deformed at 1400°C and strain rates $\sim 10^{-5} \text{ s}^{-1}$ are a factor of 20–40 times greater than in Y-TZP deformed under the same experimental conditions. It is easy to believe that dislocations cannot be activated in this system for the conditions under which superplasticity is studied. In addition, neither a sample of Y-TZP deformed by tension in the superplastic regime and cooled down under load to avoid the recovery of dislocations, or another sample quenched after deformation show no dislocation activity (Dominguez-Rodriguez *et al.*, 2013); so the activity of dislocations can also be discarded as an accommodation mechanism for superplasticity. Therefore, only the flow of point defects and solution-precipitation mechanisms are important. Depending on

Fig. 8 Deformation map for NiO with grain size of 9 μm . From Jimenez-Melendo, M., Dominguez-Rodriguez, A., Castaing, J., Marquez, R., 1986. Diffusion and creep: Application to deformation maps on NiO. *Scripta Metallurgica* 20, 739–742.

Fig. 9 As-received and tensile-deformed specimens superplastic yttria tetragonal zirconia polycrystals (YTZP), as displayed in Wakai *et al.* Reproduced from Wakai, F., Sakaguchi, S.S., Matsuno, Y., 1986. Superplasticity of yttria-stabilized tetragonal ZrO_2 polycrystals. *Advanced Ceramic Materials* 1, 259–263. Courtesy of Prof. Wakai.

which of these factors dominates during deformation, the accommodation mechanism may be regarded as the flow of point defects or solution–precipitation.

GBS Accommodated by the Diffusional Flow of Point Defects

This type of mechanism is due to a non-uniform flow of point defects: Their fundamental topological features are that the grains in the polycrystals change their neighbors and almost do not change their shape after large deformation. It was modeled in the first instance by Ashby and Verrall (1973) (thereafter A–V). The model considers a group of four grains deformed at constant pressure and stress (Fig. 5). During this flow, four irreversible processes take place:

- (1) Diffusive process by which grains temporarily change shape.
- (2) Grain or phase boundaries are sinks and sources of point defects.
- (3) Grain boundary sliding.
- (4) Fluctuations of boundary area.

Fig. 10 Experimental evidence of grain boundary sliding with microstructural invariance in superplastic YTZP. The arrow indicates the compression axis. Courtesy of Prof. Duclos.

By considering the entropy change in these four processes, the constitutive equation of the A-V model, when lattice and grain boundary diffusion are taking into account, is written:

$$\dot{\epsilon} = \frac{100\Omega}{kTd^2} \left(\sigma - \frac{0.72\gamma}{d} \right) D^l \left(1 + \frac{3\delta D^{Gb}}{dD^l} \right) \quad (10)$$

where $\frac{0.72\gamma}{d}$ is a threshold stress for the grain-switching event and γ is the grain boundary free energy.

It is clear that many studies on MgO, Al₂O₃, and UO₂ show a linear relationship between strain rate and stress which is explained in terms of diffusional models even though the measured strain rates are some orders of magnitude different from that predicted by creep models (Burton, 1977). This discrepancy is usually put down to different impurity levels or, in some cases, to the experimental technique used, e.g., in bending beam experiments. This relationship is not valid when segregation at grain boundaries occurs as in Y-TZP where a large number of studies have been performed (Jimenez-Melendo *et al.*, 1998; Jimenez-Melendo and Dominguez-Rodriguez, 1998) with a big scatter in the value of n , which ranged between 2 and 5. Probably the most plausible explanation is that the threshold stress in the A-V model ($\frac{0.72\gamma}{d}$) is not valid in Y-TZP. In Y-TZP γ is $\sim 0.15 \text{ Jm}^{-2}$ and for a grain size of $0.3 \mu\text{m}$, σ_0 is 0.3 MPa much smaller than the values found experimentally, which ranged between 3 and 9 MPa (Dominguez-Rodriguez *et al.*, 2013). In Y-TZP, the threshold stress has been obtained experimentally (Dominguez-Rodriguez *et al.*, 1998a,c) as:

$$\sigma_0 = 5 \times 10^{-4} \frac{\exp\left(\frac{120 \text{ kJ/mol}}{RT}\right)}{d} \quad (11)$$

When the threshold stress is introduced into the creep equation, the stress exponent is 2, identical to that found in metals when lattice diffusion is the rate controlling mechanism (Jimenez-Melendo and Dominguez-Rodriguez, 1998).

Solution-Precipitation Model

In the case of solution-precipitation, the secondary phase melts at temperatures lower than the matrix and, provided that the crystals are at least partially soluble in the glassy phase, creep may take place by Fig. 11:

- solution of the crystal in the liquid phase at grain boundaries under compression,
- diffusion along the liquid phase, and
- precipitation of the crystalline materials at grain boundaries under traction.

The solution precipitation model was first proposed by Raj and Chyung (1981), modified by Wakai (1994), and finally the divergence of the creep parameters in Wakai (1994) was solved by Melendez-Martinez *et al.* (2004), detailed consideration of the precipitation or solution of the crystalline material at the line defects which present as kinks in the step formed at the grain boundaries. The modified model predicts stress exponent deviating slightly from $n = 1$ as found experimentally (Melendez-Martinez *et al.*, 2002).

Applications of Superplasticity

The increasing applications of advanced ceramics in technical areas including aerospace, energy, electronics, etc., often require complex shapes to be manufactured at low prices. The extensive potential applications, together with the possibility of processing dense high-ductility ceramics with controlled microstructures, have been the driving force for the appearance of applications such as sheet forming, blowing, stamping, forging, and joining.

A good example of superplastic forming of different ceramics can be found in the first figure of Chen and Xue (1990). In this figure, flat 1 mm thick disks of Si₃N₄, 2Y-TZP:Al₂O₃, 2Y-TZP:Mullite, and 2Y-TZP + 0.3% doped with Mn, Fe, Co, Cu, and Zn, were stretched with a 6.5 mm radius punch at temperatures and forming times depending of the ceramics.

Sinter forging is a promising technique because densification and net-shaping are achieved simultaneously (Venkatachari and Raj, 1987). This technique avoids cavities and voids because sinter forging is achieved by compression producing an enhancement of strength in ceramics, Kondo *et al.* (1999) being a good example of the high strength and high fracture toughness that can be achieved in a sinter forged Si₃N₄.

Fig. 11 Schematic representation of the solution-precipitation mechanism in Wakai step model. From Melendez-Martinez, J.J., Dominguez-Rodriguez, A., 2004. Creep of silicon nitride. *Progress in Materials Science* 49, 19–107.

Fig. 12 SEM picture of the two pieces joined with different grain sizes (0.3 and 1 μm). The bar is 2 μm . From Dominguez-Rodriguez, A., Pique, E., Jimenez-Melendo, M., 1998b. Processing of multilayer of Y-TZP by superplastic flow. Scripta Materialia 39, 21–25.

Fig. 13 Scheme of the two types of compression test performed to produce the junction (isostress) and to check the strength of the junction (isostrain). From Dominguez-Rodriguez, A., Pique, E., Jimenez-Melendo, M., 1998b. Processing of multilayer of Y-TZP by superplastic flow. Scripta Materialia 39, 21–25.

As previously mentioned, it is now accepted that GBS accompanied by solution precipitation diffusional process are the mechanisms controlling superplasticity. These can start to be deployed as a novel technique to join ceramics, which takes advantage of both processes (Ye and Dominguez-Rodriguez, 1995; Dominguez-Rodriguez *et al.*, 1998a,c). When two parts in contact are superplastically deformed, the grains of one part interpenetrate those of the other, producing a rapid and perfect junction of both parts. The superplasticity does not mean that the materials need to be deformed over 100%. As soon as the material is deformed in the superplastic regime (GBS), which happens for $\epsilon > 2\%$, the junction can be achieved. A good example can be observed in Fig. 12.

Based on the mechanism controlling the superplastic behavior of fine-grained ceramics and that the creep resistance is proportional to the grain size, these two concepts have been used to join zirconia layers of different compositions and/or grain sizes to obtain a multilayer composite with a clean and strong interface and heterogeneous mechanical behavior depending on the stress application (Dominguez-Rodriguez *et al.*, 1998b).

Fully dense 3 mol% Y-TZP material 0.5 mm thick and with grain size of 0.3 μm , 0.5 μm , 0.8 μm , and 1.0 μm were joined as described in Dominguez-Rodriguez *et al.* (1998b). The composites obtained were deformed with the applied stress perpendicular to the interfaces “isostress test” and with the applied stress parallel to the interfaces “isostrain test” as indicated in Fig. 13.

These results have interesting implications in the design of materials with complex forms, for low and high temperature applications. For example, at room temperature, a short-crack ceramic (ceramic with small grain size and tough) can be superplastically joined to a long-crack ceramic (ceramic with big grain size and wear resistant) to obtain a tough and wear resistant ceramic composite. At high temperature, for the “isostress test”, the layer with the smaller grain size will control the mechanical behavior, whereas for the “isostrain test” is the layer with bigger grain size will control mechanical behavior.

For the isostrain case, where the strain and the strain rate are the same for each phase, the stress for this configuration, can be modulated by changing the volume fraction and the grain size of the different layers, details can be found in

Dominguez-Rodriguez *et al.* (1998b). This technique allows designing materials with complex shapes or Functional Gradient Materials (FGM) with anisotropic mechanical properties at low as well as high temperature.

As a final remark, it can be concluded that superplastic flow can be used to join heterogeneous zirconia layers with different mechanical properties with strong and clean interfaces junctions. As a broader implication of this work, such superplastic joining could be effectively employed to design multilayered ceramic composites for structural applications at low and high temperatures.

Future Trends in Superplastic Ceramics

- In the immediate future, the main focus in ceramic superplasticity will be the search for the right conditions to achieve “High Strain Rate Superplasticity” (HSRS) ($\dot{\epsilon} \geq 10^{-2} \text{ s}^{-1}$).

Although this phenomenon has been demonstrated in several ceramic compounds and several controlling inputs have been outlined to achieve it, we are still far from elucidating how to control this process systematically. Gaining fundamental control over HSRS can be expected to broaden the range of the applications for such ceramics.

- Improvements in ceramic powder processing technology, the routine preparation of high-purity and the new techniques for the processing of these powders such as HIP, SPS, microwave furnace, etc., will be the driving forces for a future study on nanoceramics, opening up new phenomena, and new applications.
- Finally, the future complete comprehension of superplasticity will demand a clear elucidation and justification of the basic equations describing this phenomenon. At this point, simulations at microscopic as well as mesoscopic levels may emerge as a useful tool.

Creep Behavior of Ceramic Matrix Composites

The effect of the following different types of reinforcement on the creep behavior of composites will be considered: particles reinforcement, nano-reinforcement, whisker, carbon nanotube or graphene reinforcement and continuous fiber reinforcement.

Particle Reinforced Composites

The creep behavior of particle reinforced composites has been studied by many researchers, some examples results of which will be presented. Various particle reinforcements have been added to alumina matrices. Fig. 14 shows the stress dependence of the strain rate of alumina and zirconia toughened alumina (ZTA) containing 10 vol% of zirconia. The zirconia particles ($0.5 \mu\text{m}$) are homogeneously dispersed at grain junctions between alumina grains. Both materials have the same grain size ($\sim 2 \mu\text{m}$). The addition of zirconia particles does not lead to an improvement of the creep resistance. The stress exponent $n \sim 2.5$ is similar for the matrix and the composite. Creep of alumina is controlled by grain boundary sliding (GBS) accommodated by grain boundary diffusion with the formation of cavities. The microstructures observed after creep show the presence of small cavities at the triple grain junctions and along the grain boundaries (Fig. 15).

The effect of SiC platelet reinforcement (diameter $25\text{--}45 \mu\text{m}$, aspect ratio ~ 10) on the creep behavior of alumina is shown in Fig. 16. The creep resistance is increased by more than one order of magnitude. The stress exponent of the composites ($n = 2.5$) is higher than for monolithic alumina ($n = 1.5$). The decrease of the creep rate is due to unloading of alumina grains due to load transfer from the matrix to the platelets.

Fig. 14 Stress dependence of the strain rate in bending of alumina and a ZTA composite at 1473K. From Fantozzi, G., Chevalier, J., Olagnon, C., Chermant, J.L., 2000. Creep of ceramic matrix composites. Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), Comprehensive Composite Materials, vol. 4. Oxford: Elsevier.

Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), *Comprehensive Composite Materials*, vol. 4. Oxford: Elsevier.

Fig. 16 Stress dependence of compression creep rate of alumina-SiC platelet composites at 1623K : (1) alumina; (2) alumina + 10 vol% SiC_p; alumina + 20 vol% SiC_p. From Fantozzi, G., Chevalier, J., Olagnon, C., Chermant, J.L., 2000. Creep of ceramic matrix composites. Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), *Comprehensive Composite Materials*, vol. 4. Oxford: Elsevier.

Another example concerns the zircon-based composites. Due to the presence of an intergranular glassy phase, zircon exhibits a low creep resistance. The creep mechanism of zircon is GBS which can be prevented by second phase interlocking and glassy phase modification (amount and viscosity). Composites reinforced with 9 wt% alumina can show a strong increase of the creep resistance (3 orders of magnitude).

The creep behavior of Si₃N₄ reinforced with particles or platelets has been studied by several authors (Fantozzi *et al.*, 2000). The creep resistance depends on the presence and the composition of grain boundary phase (glassy or crystalline phase). The reinforcement is essentially due to a load transfer from the matrix to the platelet or particle.

Nanocomposites

Nanocomposites are composed of micro-sized matrix grains with nano-sized reinforcing particles. Ohji *et al.* (1994) have studied the creep behavior of an alumina reinforced by 17 vol% SiC nanoparticles (average particle size ~ 100 nm). The SiC particles were located within the alumina grains (~ 2 µm) and along the grain boundaries. The nanocomposites exhibit a higher creep resistance (Fig. 17) compared to alumina (the failure strain was 0.5% against 4% for alumina). After creep, very few cavities, and microcracks are observed for the nanocomposites, in contrast to pure alumina. The creep rate with the addition of the nanoparticles is three to

Fig. 17 Stress dependence of strain rate in tension (curves 1 and 1') or flexure (curves 2 and 2') of alumina and nanocomposite at 1473K. From Fantozzi, G., Chevalier, J., Olagnon, C., Chermant, J.L., 2000. Creep of ceramic matrix composites. Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), *Comprehensive Composite Materials*, vol. 4. Oxford: Elsevier.

four orders of magnitude lower than for alumina with the same grain size. The stress exponent measured for the nanocomposite ($n = 3.1$) in tension is higher than for alumina ($n = 2.2$).

The role of the SiC nanoparticles is difficult to specify, but a rotation of intergranular nanoparticles occurs that “plunge” into the alumina matrix as shown by Ohji *et al.* (1994) and provokes the formation of small cavities around the particles. This process leads to a particle pinning of the grain boundaries and to hindrance of GBS and so to a significant increase in creep resistance. The presence of SiC nanoparticles can also modify the chemistry of grain boundaries and decrease the boundary diffusivity leading to a reduction of cavity formation. The enhancement of grain boundary cohesion by SiC nanoparticles inhibits GBS and provokes plastic deformation by dislocation motion. This can explain the high n values measured for the nanocomposites, values consistent with creep mechanisms involving dislocation glide or climb.

The creep behavior of nanocomposites with a Si_3N_4 matrix reinforced by SiC nanoparticles has been studied by several authors (Fantozzi *et al.*, 2000). The nanocomposites exhibit a good creep resistance due to an increase in grain interlocking by SiC nanoparticles.

Whisker, Carbon Nanotube, and Graphene Reinforced Composites

First, the case of SiC whiskers (SiC_w) reinforced alumina will be considered. The creep rate of alumina is strongly reduced by the addition of SiC_w (more than two orders of magnitude lower) as shown by Fig. 18. The decrease depends on the whisker content, size and shape and on the matrix grain size. The stress exponent n (~ 2) is similar to that of alumina except at high temperature where n increases (~ 7 to 8). As shown by De Arellano-Lopez *et al.* (1990), these high n values obtained by using flexural creep tests are related to the stress gradient from tension to compression. Smaller values (~ 2) are obtained by compression tests.

The improvement of the creep resistance can be attributed to the inhibition of GBS by the pinning and locking action of the whiskers located along the grain boundaries. This can explain the important difference in strain to failure observed for alumina ($> 3\%$) and for the composites ($< 0.5\%$) as shown by Fig. 18. The high stress exponent observed at high temperature can be linked to creep cavitation at matrix-interfaces. The whiskers act as stress concentration sites leading to more extensive cavitation and cracking.

Similar enhancement in creep resistance is observed for other composite matrices (Fantozzi *et al.*, 2000).

Secondly, creep in carbon nanotube (CNT) reinforced ceramic composites will be examined. As mentioned by Castillo-Rodriguez *et al.* (2018), the influence of incorporation of CNTs in ceramic composites is not clear. Indeed, Mazaheri *et al.* (2011) have shown that CNTs/nanostructured 3Y-TZP zirconia composites exhibit a significant reduction of creep strain but other authors found that CNTs enhance GBS and do not act as reinforcement phases. Mazaheri *et al.* consider that the higher creep resistance of the CNTs/3Y-TZP composites is due to the pinning effect of CNTs blocking GBS. It must be mentioned that the creep behavior considered by Mazaheri *et al.* took place at very low stress (6 MPa) whereas for most of studies the considered creep stress range is much higher (10–400 MPa).

Recent results (Gopalan and Choskhi, 2018; Castillo-Rodriguez *et al.*, 2018) show that the creep resistance at high stress is not influenced by the addition of CNTs to an alumina matrix (Fig. 19). For the same matrix grain size (0.5 μm), the stress exponent

Fig. 18 Flexural creep curve for alumina and SiC_w-alumina composites at 1473K and 100 MPa under air: (1) alumina; (2) 12 vol% SiC_w; (3) 30 vol% SiC_w. From Fantozzi, G., Chevalier, J., Olagnon, C., Chermant, J.L., 2000. Creep of ceramic matrix composites. Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), *Comprehensive Composite Materials*, vol. 4. Oxford: Elsevier.

Fig. 19 Strain rate–stress curves for alumina and CNT-alumina nanocomposites tested at different temperatures. From Castillo-Rodriguez, M., Munoz, A., Dominguez-Rodriguez, A., 2018. Creep study on alumina and alumina/SWCNT nanocomposites. *Journal of The European Ceramic Society* 38, 5497–5502.

and the activation energy of alumina and CNT-alumina composites are very similar. The GBS accommodated by lattice diffusion (Nabarro–Herring type), is the predominant creep mechanism.

Thirdly, the creep behavior of graphene oxide-reinforced alumina (or zirconia) composites was recently studied by Cano-Crespo *et al.* (2017, 2018). Graphene-reinforced zirconia composites do not exhibit an improvement of the creep resistance compared to monolithic zirconia. The dominant effect of graphene is a lubricant effect increasing the grain boundary mobility. Concerning graphene-reinforced alumina composites, the creep resistance is improved compared to alumina at intermediate temperatures whereas at high temperatures there is no reinforcement. The dominant creep mechanism is GBS accommodated by diffusion and the creep parameters for the composites are similar to those of pure alumina.

Long Fiber Reinforced Composites

Long fiber ceramic composites often reinforced with SiC Nicalon fibers have been studied either with a glass-ceramic matrix or a crystalline ceramic matrix (Fantozzi *et al.*, 2000). The creep processes in these composites are complex and cannot be treated by conventional creep models. Several models have been proposed for continuous ceramic fiber-reinforced CMCs, first based on the rule of mixtures, then on the shear-lag model and then based on damage mechanics. These models must take into account the stress redistribution between fibers and matrix occurring during creep and the processes of damage accumulation. This stress redistribution between the composite constituents depends on the creep mismatch ratio (CMR) defined on the ratio of the fiber creep rate to that of the matrix. CMR is time, stress and temperature dependent.

Fig. 20 Creep rates versus stress for $\text{SiC}_f\text{-MLAS}$ composite. B: bending test, V: vacuum for two architectures (1D and 2D). From Fantozzi, G., Chevalier, J., Olagnon, C., Chermant, J.L., 2000. Creep of ceramic matrix composites. Chapter 7: Carbon/carbon, cement, and ceramic matrix composites. In: Warren, R. (Ed.), *Comprehensive Composite Materials*, vol. 4. Oxford: Elsevier.

Fig. 21 Tensile creep strain versus time tested at 1300°C for coated specimen. From Jing, X., Yang, X., Shi, D., Niu, H., 2017. Tensile creep behavior of three-dimensional four-step braided SiC/SiC composite at elevated temperature. *Ceramics International* 43, 6721–6729.

When $\text{CMR} < 1$, the matrix has a higher creep rate than the fibers and there is a transfer from the matrix to the fibers, which controls the deformation and the rupture of the composites. The stress in fiber ceramics increases and fiber breakage occurs. This is also the case with glass-ceramic matrix composites.

An example of creep behavior for a glass-ceramic matrix composite is given in Fig. 20. $\text{SiC}_f\text{-MLAS}$ composites (magnesium-lithium aluminosilicate + Nicalon NLM 202 SiC fibers) were studied by three-point bending under vacuum for two architectures 1-D unidirectional orientation and bi-directional orientation $(0-90^\circ)_6$, between 1173K and 1473K and at stresses from 25 to 400 MPa. For the 1-D architecture, only one domain is observed for the creep rate versus stress curves whereas two domains are observed for the 2D architecture. The initial loading affects the creep behavior if the stress exceeds the linearity stress limit. The shear stresses drive the matrix microcracking and thus the sequence of the creep stages.

When $\text{CMR} > 1$, case of composites with very creep resistant matrices (ceramic matrices), a load transfer from the fiber to the matrix occurs, the matrix stress increase can lead to microcracking. The creep behavior is dominated by matrix properties. An example of such behavior is given by Fig. 21. Jing *et al.* (2017) which shows the tensile creep strain versus time curves for a SiC_f (Nicalon)/ SiC composite (coated with an environmental barrier coating) at 1300°C in air. The creep resistance of the porous

matrix is low. The stress exponent deduced from these results is close to 1 and similar to the Nicalon fibers (Newtonian-type viscous flow), the creep of the composites being controlled by the fiber creep.

The same observations have been made by Morscher (2010) on a 2D-woven SiC/SiC composite at 1315°C under air, the dominant factors controlling creep and rupture behavior of the composite are creep and rupture of the fibers.

Furthermore, the creep behavior of long fiber reinforced composites depends not only on the creep properties of constituents but also on their textile structures. This creep behavior is also strongly influenced by the oxidation resistance of the constituents (fiber, interface and matrix), which limits the composite lifetime at high temperature in air. The oxidation embrittlement propagates through matrix microcracking. Several oxygen diffusion barriers can be used to protect the composites against oxidation: glass sealant, SiBC matrix, coatings (Jing *et al.*, 2017). The oxide-oxide composites with high oxidation resistance at elevated temperatures can be considered if creep resistant fibers are developed.

Processing and Creep of Silicon Nitride

Commercial Si_3N_4 is normally made by liquid-phase sintering at temperatures between 1800 and 2000 °C. Rare-earth oxides, Al_2O_3 , and MgO are used as sintering aids. These react with the silica normally present on the surface of the silicon nitride grains to produce an intergranular silicate phase that aids sintering. Hot isostatic pressing (HIPing) or high-pressure nitrogen, 1–8 MPa, is used to prevent decomposition of the Si_3N_4 at these temperatures. Microstructural studies on liquid-phase sintered Si_3N_4 show that a silicate phase wets almost all of the grains of Si_3N_4 . An amorphous silicate layer, about 1 nm thick, separates the grains of Si_3N_4 . The silicate phase in multigrain junctions partially devitrifies at 1200–1400 °C, forming a variety of crystalline phases. Because the sintering aid softens at a lower temperature than the Si_3N_4 grains, creep depends on the refractoriness and amount of the sintering aids. Compositions containing only rare-earth oxides are the most creep resistant. The addition of Al_2O_3 or alkaline earth oxides lowers both the sintering temperature and the creep resistance. However, these are necessary to improve toughness or wear resistance and so are used even though creep behavior is degraded.

Studies on commercial grades of silicon nitride indicate that the mechanisms of creep in tension and compression are different. In compression, the creep rate is a power function of the applied stress, with a stress exponent close to unity. The creep mechanism is believed to be due to solution-precipitation, in which Si_3N_4 dissolves into the silicate phase at areas on the grains where compressive stresses are high. The Si_3N_4 then diffuses through the silicate phase and reprecipitates on Si_3N_4 grains where stresses on the grains are very much lower or where the stresses are tensile in character. In tension, the creep rate depends exponentially on the applied stress (Figure 1), and is primarily a consequence of cavity formation and the flow of the silicate phase away from the cavitation site. For the same magnitude of applied stress and temperature, creep in tension can be hundreds of times greater than creep in compression. Meléndez-Martínez and Domínguez-Rodríguez (2004) and Moreira da Silva *et al.* (2010) indicate the importance of the nature of the second silicate phase, with the latter clearly endorsing the work of others relating to the realization of lower creep rates when the second (grain boundary) phase is a crystalline silicate rather than a vitreous one.

Processing and Creep of Silicon Carbide

Solid-state sintering of SiC through the use of sintering aids such as boron (or aluminum) and carbon produce grades of SiC with very high creep resistance. These elements modify grain boundary and surface energies, and enhance volume diffusion rates to favor densification of SiC. Carbon also converts SiO_2 to SiC to hinder the formation of glass at grain boundaries. In these materials, the SiC grains are in direct crystalline contact; there is no second phase at the grain boundaries. Hence, molecular processes that control solid-state sintering, i.e., grain boundary and bulk diffusion, also control the compressive creep of sintered SiC. Large-grain-size SiC (made by chemical vapor deposition) retards diffusional creep. Then, dislocation motion controls the creep process.

High-density silicon carbides can be made at lower temperatures by reaction bonding SiC grains with silicon. Because they are made by the infiltration of molten silicon into carbonized, partially bonded SiC, all grades of reaction-bonded SiC consist of an interconnected structure of silicon and SiC, in which the grains of SiC are directly bonded. Residual silicon fills the remaining structure. Reaction-bonded SiC is impermeable to oxygen and, hence, resistant to internal oxidation at high temperatures.

The mechanical behavior of reaction-bonded SiC depends on the amount of metallic silicon in the microstructure. With less than 10% of silicon by volume, substantial bonding occurs between the grains. Creep occurs by the deformation of the SiC, which is the same mechanism of creep as occurs in the solid-state sintered material. However, in the absence of sintering aids to enhance diffusion, creep rates of the reaction-bonded material can be less than that of the sintered material (Figure 2).

As the volume fraction of silicon is increased, less SiC is available to bond the SiC grains together. The decreased bonding between SiC grains permits these bonds to rupture as creep commences. The SiC grains slide over one another and the deformation of the silicon that accompanies the sliding process then controls creep. Because silicon deforms more readily than SiC, reaction-bonded SiC with large volume fractions of silicon is less creep resistant than sintered SiC (Figure 2). Like liquid-phase sintered Si_3N_4 , tensile creep of reaction-bonded SiC can be hundreds of times faster than compressive creep. Here too, the difference in behavior is a consequence of cavity formation during tensile creep.

Figure 1 Tensile and compressive creep behavior of silicon nitride (data taken from Yoon *et al.*, 2000).

Figure 2 Comparison of secondary creep rates for covalent (SiC and Si₃N₄) and ionic (Al₂O₃ and ZrO₂) materials: HP, hot pressed; RB, reaction bonded; S, sintered (data for SiC and Si₃N₄ taken from Wiederhorn *et al.* (1999), for Al₂O₃ and ZrO₂ from French *et al.* (1994)).

Creep Rupture of Silicon Nitride and Silicon Carbide

Little is known of the mechanism of failure of Si₃N₄ and SiC at creep temperatures. The final stages of failure always involve the growth of a macroscopic crack; however, the defects that cause failure at room temperature and at high temperature are not necessarily the same. Experimental studies are still needed to clarify the mechanisms of failure. However, for all structural ceramics, a logarithmic plot of creep rate vs. failure time fits a straight line, or a set of straight lines depending on temperature. Therefore, higher creep resistance leads to an improved lifetime. This finding has determined the main direction of research and development to produce better high-temperature commercial grades of Si₃N₄.

For additional information on creep of Si₃N₄ and SiC, readers should consult the review articles by Davis and Carter (1988), Hynes and Doremus (1996), Luecke and Wiederhorn (1999), Wiederhorn *et al.* (1999), Meléndez-Martínez and Domínguez-Rodríguez (2004), and Ramírez-Rico and Martínez-Fernández (2014).

Dislocations in Ceramic Materials

Jacques Rabier, Department of Physics and Mechanics, The French National Centre for Scientific Research, University of Poitiers, Chasseneuil Cedex, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

Ceramics are based on compounds of high thermodynamic stability, with strong chemical bonds having dominant ionic or covalent character. This leads to specific characteristics, namely ceramics are generally brittle and very resistant to corrosion. Ceramic bodies are constituted of small crystalline grains (sizes of 1 μm or larger) mixed with glassy phases, in amounts which depend on the materials, the processing and the applications. At high temperatures, they are easy to deform because grain boundary sliding becomes an important mechanism; some grain deformation is required to accommodate local strains, which can be achieved, in particular, by dislocation motion. At intermediate temperatures, the fracture toughness of crystalline ceramic materials can be increased by dislocations generated at crack tips. These two examples show the importance of dislocations for mechanical applications of ceramics. The corresponding market is still small compared to that of electronic and optical ceramics, where dislocations have not attracted much attention in spite of their influence on the performance of devices. Following studies in metals and semiconductors, dislocations in ceramics have been the object of many investigations. In this article, we summarize the features which explain why they have motivated basic research efforts and we illustrate the acquired knowledge by selecting examples on a number of compounds (NiO, zirconia, Al_2O_3 , SiC, Si_3N_4 , superconductors).

General Features

Dislocations in ceramics share many aspects with those in metals and semiconductors in explaining plastic deformation properties. However, most ceramic materials have low-symmetry crystal structures with large unit cells, producing a number of consequences regarding dislocations, as reviewed by Bretheau *et al.* (1979) and Mitchell and Heuer (2004). The Burgers vectors b can be as large as 1.5–2 nm, with correspondingly several extra half-planes inserted for edge dislocations. This calls for a complexity in the dislocation of core configurations (hollow cores, broken bonds, nature of atoms, position of slip plane, etc.), as well as for jogs and kinks along the line which has to be addressed. The elastic energy of such dislocations can be very large; taking μb^2 (μ being the elastic shear modulus, between 100 GPa and 200 GPa) as the energy per repeat distance along the line, typical values are 22 eV for NiO, 100 eV for basal slip in $\alpha\text{-Al}_2\text{O}_3$, and 600 eV for $\text{Y}_3\text{Fe}_5\text{O}_{12}$ or $\text{Gd}_3\text{Ga}_5\text{O}_{12}$ (GGG), compared to less than 5 eV for f.c.c. metals ($1 \text{ eV} = 1.6 \times 10^{-19} \text{ J}$). An immediate consequence is that dislocation dissociation is expected in order to decrease the amount of elastic energy stored in deformed crystals. This dissociation has been observed in many cases, with stacking faults in the glide plane (Fig. 1), and also out of the glide plane (Fig. 2), generally when high temperatures and large point defect concentrations make diffusivity fast enough for the climb of partial dislocations. The dissociation by climb in spinels has been first reviewed by Bretheau *et al.* (1979). Later, Veyssi re (1988) suggested that climb dissociation, by considerably reducing the mobility of dislocations in MgAl_2O_4 , explains the anomaly in the variation of the CRSS (critical resolved shear stress) with temperature that he observed for single crystals deformed under hydrostatic pressure between 20 C and 1000 C. In various cases, no dissociation was observed, although many properties (very strong thermal activation of the flow stress, violation of Schmid's

Fig. 1 Schematic representation on an edge dislocation dissociated by glide into three collinear partials: the stacking fault is indicated by the gray area. This corresponds to a $\langle 1 - 010 \rangle$ dislocation activated for prism plane slip in sapphire; an edge dislocation is formed by inserting three different layers. For the sake of simplicity, the distances between the partials have been reduced to unrealistic small values of the order of $1/3 \langle 1 - 010 \rangle$. Reproduced from Lagerlof, K.P.D., Mitchell, T.E., Heuer, A.H., *et al.*, 1984. Stacking fault in sapphire ($\alpha\text{-Al}_2\text{O}_3$). *Acta Metall.* 32, 97–105.

Fig. 2 The dislocation in Fig. 1 is dissociated by climb of the partials. Two stacking faults appear which are indicated by the gray areas. This figure corresponds to one of the three possible climb configurations for prism plane slip dislocations in sapphire. Reproduced from Lagerlof, K.P.D., Mitchell, T.E., Heuer, A.H., *et al.*, 1984. Stacking fault in sapphire (α -Al₂O₃). *Acta Metall.* 32, 97–105.

law, etc.) lead to the assumption of core extension below the detection limit of transmission electron microscopy (TEM). In the complex structures of ceramics, several possibilities may also exist as regards the atomic configuration of the glide plan. Depending on the location of the shear, the core structures of dislocations can be as different as the resultant glide properties (dissociation, Peierls stresses (see Section “Brittle Compounds”). Then although the same glide system is activated, different mechanisms can be operative, depending of the shear location which in turn may depend on stress and temperature (see, e.g., Duesbery and Joos, 1996).

Plastic deformation occurs when dislocations glide and multiply in given planes, the characteristics determining the easiest plane follow well-established rules, such as electrostatic interactions, for example, in cubic zirconia (Dominguez Rodriguez *et al.*, 1991) or low elastic energy, especially in extremely anisotropic crystals such as TeO₂ (Peter *et al.*, 1986). Among exceptions, one finds α -Al₂O₃ (see Section “Ductile Compounds”) where the observation of slip on the prism plane is unexpected in view of the energies required for dislocation glide (Heuer *et al.*, 1998). Finally, there may be crystallographic constraints on glide behavior, due to low symmetry, which make glide in the positive and negative slip direction (i.e., along $+b$ and $-b$) different; this is the situation for slip on the system (0001) $\langle 011-0 \rangle$ in α -Al₂O₃ (Castaing *et al.*, 1997).

The first cause for the brittleness of ceramics is that the number of slip systems is insufficient for the deformation of polycrystals, even for materials such as MgO, NiO, etc., which have a cubic crystal structure. When the temperature is increased, plastic anisotropy is decreased and atomic diffusion is effective, thus allowing plastic deformation. A second cause for the brittleness is the covalent character of the chemical bonds in most ceramic materials; this is associated with large Peierls stresses, or lattice friction, which impedes dislocation glide at low temperature. Even single-crystal specimens fracture before plastic deformation, a behavior which is common to semiconductors as well. Brittle/ductile transitions have been observed at 800°C for cubic zirconia single crystals (Marrow *et al.*, 1994) and around 1000°C for α -Al₂O₃ sapphire (Kim and Roberts, 1994). Fracture can be suppressed by the use of hydrostatic pressure, which induces plasticity in alumina well below 1000°C (Castaing *et al.*, 2000). Experiments of this kind have promoted the development of new models to explain the thermal activation of dislocation glide based on the formation of kink pairs and kink motion with large lattice friction (Mitchell and Heuer, 2004; Castillo Rodriguez *et al.*, 2007). In the following, we give examples to illustrate these general features about dislocations in ceramic materials.

Cubic Crystals

Ductile Compounds

There have been many investigations of dislocations and plasticity in ionic crystals such as LiF, NaCl, MgO, CaF₂, etc.; these materials have been available as single crystals for decades and they show extensive ductility, as reviewed by Castaing (1981). Slip occurs along the $\{11-0\} \langle 110 \rangle$ system which can be activated in compression along $\langle 001 \rangle$. It has been activated at temperatures as low as 4.2 K for NaCl type oxides, for example, CoO (Dominguez Rodriguez, *et al.*, 1988) and NiO (Jimenez Melendo *et al.*, 1992), with CRSS around 100 MPa at 4.2K. This unusual ductility for ceramic materials can be ascribed with the highly ionic chemical bonds in these compounds, with the absence of strong obstacles to dislocation glide. When the compression axis is parallel to $\langle 111 \rangle$, glide on $\{11-0\} \langle 110 \rangle$ is prevented from being activated, and dislocations can glide in the

secondary slip system $\{0\ 0\ 1\} \langle 110 \rangle$. The plastic anisotropy can be very large, with ratios of the CRSS for $\{0\ 0\ 1\}$ slip to that for $\{11\ 0\}$ slip reaching values as large as fifty in MgO around 300°C (Foitzik *et al.*, 1989). This is consistent with the fact that dislocations in compounds with the NaCl structure are dissociated on $\{11\ 0\}$ but not on $\{0\ 0\ 1\}$ planes, with the exception of PbS (Foitzik *et al.*, 1989). However, there is no clear observation of such dissociation using weak beam TEM (with its limit of detection around 2 nm) (Foitzik *et al.*, 1989). Dislocations have been observed by high-resolution TEM in several oxides, including SrTiO₃, MgO, CoO, and NiO, where extension of the cores was detected (Takeuchi *et al.*, 1989).

Atomistic simulations of dislocation properties have been performed showing results in agreement with experimental facts (Castaing, 1981). No dislocation dissociation has been found under normal conditions. Core energies and Peierls stresses have been calculated for several materials, with Peierls stress values around 60–70 MPa for MgO. Atomistic simulations have also enabled the elucidation of mechanisms such as diffusion along the dislocation core in MgO (Rabier and Puls, 1985) and dislocation-point defect interactions in NiO (Rabier *et al.*, 1990). Nickel vacancies, which are associated with nonstoichiometry in NiO, could be present in higher concentrations on edge dislocations and lead to a very defective core, with consequences to their glide mobility. Recently, TEM techniques are now available to probe non-stoichiometry on dislocation cores (Jia *et al.*, 2005), but such measurements have not been reported for NiO.

Brittle Compounds

Several oxides (e.g., Cu₂O, UO₂, MgAl₂O₄, Y₂O₃) are brittle at low temperatures but show extensive plasticity at high temperatures (Bretheau *et al.*, 1979); many of them have non compact cubic structures and are largely covalently bonded, which is at the origin of their brittleness. Yttria stabilized cubic zirconia (ZrO₂ with more than 9 mol% Y₂O₃) is another example of a ceramic material which has been studied in detail; although it is brittle below 800°C in bending (Marrow *et al.*, 1994), single crystals have been deformed in compression down to 500°C at normal pressures (0.1 MPa) and down to 250°C under 0.4 GPa hydrostatic pressure, with flow stresses around 700 MPa and 3000 MPa, respectively. The work on dislocations and plasticity in zirconia has been reviewed by Messerschmidt *et al.* (1997, 1998). Cubic zirconia has the CaF₂ crystal structure and deforms by glide of $1/2 \langle 110 \rangle$ dislocations with $\{0\ 0\ 1\}$ as the primary glide plane; $\{1\ 1\ 1\}$ and $\{1\ 1\ 0\}$ planes can also be activated, the plastic anisotropy disappearing above 1400°C. This behavior is similar to that of CaF₂ single crystals, for which the CRSS decreases in the order $\{1\ 1\ 0\} > \{1\ 1\ 1\} > \{1\ 0\ 0\}$, Schmid's law for these slip planes being obeyed in all cases, as revealed by tests along five compression axes (Munoz *et al.*, 1994). The large amount of point defects in zirconia, due to yttria, does not affect the choice of the slip plane. However, yttria hardens zirconia; at 1400°C, the flow stress of single crystals increases from 200 MPa to 350 MPa when the concentration of Y₂O₃ increases from 9 mol% to 22 mol% (Messerschmidt *et al.*, 1998). At $T > 1400^\circ\text{C}$, although solute drag and recovery play important role, yttria continues to harden zirconia crystals (Gomez Garcia *et al.*, 1997). Detailed examinations of the dislocation structure by TEM have permitted elucidation of some of the mechanisms controlling the rate of deformation. Dislocation dissociation has not been found; the violation of Schmid's law for $\{0\ 0\ 1\}$ slip, around 400°C under hydrostatic pressure, is probably due to a core extension smaller than the limit of detection of the experimental techniques.

The case of partially stabilized zirconia (ZrO₂ with less than 8 mol% Y₂O₃) has also been studied in detail and reviewed by Messerschmidt *et al.* (1997). For 3–6 mol% Y₂O₃, tetragonal precipitates (*t*-ZrO₂) appear, with morphologies at 1600°C that depend on the annealing time (Martinez Fernandez *et al.*, 1995). These precipitates harden single crystals as they develop with time, the flow stress increasing above 300 MPa. The hardening has been explained by the classical models, namely dislocations cutting the precipitates where they must glide as pairs of $1/2 \langle 110 \rangle$ partials separated by a stacking fault or creation of Orowan loops around precipitates, the balance between the two mechanisms depending on the sizes and spacings of the precipitates.

Cubic perovskite structure materials are of great interest because of their presence in the earth lower mantle and because of their numerous uses in electronic ceramics; they can be plastically deformed at high temperatures. It was surprising to discover that SrTiO₃ could be deformed down to 43K at normal pressure with a gap in ductility between 1000K and 1200–1400K (Gumbsch *et al.*, 2001; Brunner, 2006). This behavior has been ascribed to modifications of the dislocation core structure with the temperature. This has been confirmed recently by atomistic calculations (Hirel *et al.*, 2016) showing a change in the core structure from glissile glide-dissociated into a sessile, climb-dissociated configuration at high temperature.

The garnet structure can be used to exemplify the consequences of large strain energies of dislocations on the plastic behavior of ceramics. This structure can be regarded as a b.c.c. one with a large unit cell parameter, usually $a_0 > 1.2$ nm, with a noncompact distorted oxygen sublattice (Rabier *et al.*, 1976). As a consequence, the smallest Burgers vector $1/2 \langle 111 \rangle$ has a magnitude larger than 1.0 nm. Although these Burgers vector can dissociate according to the reaction: $1/2 \langle 111 \rangle \rightarrow 1/4 \langle 111 \rangle + 1/4 \langle 111 \rangle$, the strain energy of a dissociated configuration is still very high as compared to metals.

High-temperature deformation of Gd₃Ga₅O₁₂ (GGG) ($T_M = 1780^\circ\text{C}$, $a_0 = 1.237$ nm, $|b| = 1.07$ nm) in the temperature range 1300–1500°C ($0.79\text{--}0.92T_M$) has been investigated by creep as well as at constant strain rate in air as a function of compression xxqaxis $\langle 100 \rangle$ and $\langle 110 \rangle$. The observed glide planes are $\{110\}$, $\{112\}$, $\{123\}$ similar to those observed in b.c.c. metals (Garem *et al.*, 1982).

The activated glide systems depend on the orientation of compression axis and the slip system with the highest Schmid factor is not always activated. This observed violation of the Schmid law is analogous to what is found in b.c.c. metals at low temperature (see Dislocations in Metals and Metallic Alloys) and as in b.c.c. metals, long straight screw segments were found in GGG belonging to Frank–Read sources in samples deformed at a constant strain rate (Rabier and Garem, 1984).

In a 'low-temperature deformation b.c.c. metal mechanism', the screw dislocations located along a threefold axis are weakly dissociated into a nonplanar sessile configuration. Dislocation glide occurs if the applied force is sufficient to transform this sessile configuration into a glissile planar one by recombination of the partials. The energy needed to recombine the dislocation core is of the order of μb^3 . For b.c.c. metals, there is a transition temperature between the sessile core screw dislocations controlling deformation and a high-temperature regime where they do not play any role. The transition temperature is a function of μb^3 (Kubin, 1976) and it has been shown that the sessile core structure of screw dislocations controls the plastic properties for values of the ratio $KT/\mu b^3$ lower than 5×10^{-3} .

At the melting temperature the large values of the dislocation strain energies in GGG yield for the ratio $kT/\mu b^3$ respectively 2.7×10^{-4} ($b = 1/2 \langle 111 \rangle$) and 2×10^{-3} ($b = 14 \langle 111 \rangle$) which are lower than the critical value for b.c.c. metals. This shows that a dissociation recombination mechanism is expected to control plastic properties of GGG up to the melting point. The threefold dissociation mechanisms, usually observed for metals only at low temperature, are to be considered also at high temperature for materials with large Burgers vectors although such mechanisms can be hindered by diffusion processes.

Low Symmetry Crystals

α -Alumina

Sapphire, which is the single-crystalline form of α -Al₂O₃, as well as alumina ceramics have wide-ranging applications. Its crystal structure can be described using a rhombohedral unit cell with threefold symmetry; the description using a hexagonal unit cell is convenient, but can induce incorrect ideas on atomistic mechanisms (Heuer *et al.*, 1998). Deformation of alumina single crystals has received considerable interest because it is a model material for many low-symmetry minerals. Sapphire is brittle in bending below 1030–1100°C (Kim and Roberts, 1994). It can be deformed in compression by $(0\ 0\ 0\ 1) \langle 2 - 110 \rangle$ basal slip above 890°C at normal pressure, with adequate crystalline orientations to avoid rhombohedral twinning; twinning can be activated at 900–1100°C under shear stresses between 10 MPa and 60 MPa, dislocations being strong obstacles to twin extension (Castaing *et al.*, 2002). The shortest Burgers vector is $1/3 \langle 2 - 110 \rangle$ ($b = 0.475$ nm). The secondary system is $\{12 - 10\} \langle 1 - 010 \rangle$ prism plane slip, which is unexpected because its Burgers vector ($b = 0.822$ nm) is longer than three other repeat distances in the structure (Heuer *et al.*, 1998), and glide on prism planes can, in principle, occur along the same direction as in the basal plane. At 1400°C or above, Cadoz *et al.* (1982) found by TEM that $\langle 1 - 010 \rangle$ dislocations gliding in $\{12 - 10\}$ decompose into two $1/3 \langle 2 - 110 \rangle$ basal dislocations, especially for large deformations (shear stresses above 100 MPa). At small strains, the microstructure consists of prism plane slip dislocations which are dissociated into three collinear partials with Burgers vectors of the type $1/3 \langle 1 - 010 \rangle$ (Fig. 2). This dissociation corresponds to a decrease in energy equivalent to that resulting from the decomposition into two basal slip dislocations (Lagerlof *et al.*, 1984). For specimens deformed at 1400°C, climb dissociation has been observed by TEM both for $1/3 \langle 2 - 110 \rangle$ basal slip dislocations (into $1/3 \langle 1 - 010 \rangle$ and $13 \langle 1 - 100 \rangle$) and for $\langle 1 - 010 \rangle$ prism plane slip dislocations (Fig. 2), with distances between partials of 8 nm and 30 nm, respectively (Lagerlof *et al.*, 1984). This corresponds to dislocation configurations with energies lower than those for glide dissociation (Fig. 1), and is facilitated by high-temperature diffusion. In both cases, the stacking fault planes are distinct from the $(0\ 0\ 0\ 1)$ basal plane. This agrees with the fact that the stacking fault energies in sapphire are low on the prism planes; values between $0.1\ \text{J m}^{-2}$ and $0.2\ \text{J m}^{-2}$ are deduced from TEM in agreement with computed values (Jhon *et al.*, 2005). On the basal plane, the stacking fault energy is only available from computations that give high values ($\approx 2\ \text{J m}^{-2}$) (Heuer *et al.*, 1998). Although climb dissociation has been largely observed in alumina, no anomaly has been found for the variations of the CRSS with temperature, either for basal slip, or for prism plane slip, contrary to the situation for other materials (Veyssi re, 1988).

Below 1000°C alumina ceramics and single crystals have been plastically deformed under 1.5 GPa hydrostatic pressures (Lagerlof *et al.*, 1994; Castaing *et al.*, 2000); CRSS values as high as 3000 MPa were obtained for prism plane slip at 200°C. For basal slip orientations, extensive twinning was obtained below 800°C, including basal twinning which had not been observed previously after mechanical tests (Castaing *et al.*, 2004). This discovery stimulated a new understanding of basal slip and twinning based on the glide of $1/3 \langle 101 - 0 \rangle$ partial dislocations on an electrically neutral plane within the puckered Al ion array. This leaves half of the Al ions on the surfaces of the two half-crystals gliding on each other, rather than all the Al ions on one half, as suggested by the misleading use of the hexagonal unit cell (Heuer *et al.*, 1998). This is particularly true for the basal twinning mechanism, where complicated models involving several types of dislocations have been suggested in the past by many authors. The new model merely requires the glide of $1/3[101 - 0]$ partials on every other $(0\ 0\ 0\ 1)$ basal plane. This, in turn, can be accomplished by a Frank–Read type source involving only partials which jump from one plane to the next available plane after the emission of one loop (Heuer *et al.*, 1998). Indeed, such sources have been observed by TEM (Fig. 3) supporting the new understanding for basal slip and twinning (He *et al.*, 2002).

At low temperature, slip dislocations on the prism plane have been found to dissociate by glide (Fig. 1). The fact that prism plane slip becomes easier than basal slip below 600°C, under hydrostatic pressure, and the strong thermal activation of dislocation glide, have suggested that the cores of the rate controlling dislocations are extended. However, weak-beam TEM of basal slip dislocations never revealed any core extension (Lagerlof *et al.*, 1994). High-resolution TEM on basal slip dislocations has confirmed the already observed climb dissociation with a distance of 4.7 nm between the two partials (Nakamura *et al.*, 2002); no perfect dislocation or glide dissociation was found. A molecular-dynamic simulation of a basal slip dislocation does not give any

Fig. 3 Weak-beam TEM of a prism plane slip dislocation in sapphire dissociated into three partials lying in a basal twin boundary. This feature is a source for basal twinning. Sapphire was deformed at 700°C under a stress of 1095 MPa. Reproduced from He, A., Lagerlof, K.P.D., Castaing, J., Heuer, A.H., 2002. Considerations of the double cross slip mechanism for basal and rhombohedral twinning in sapphire. *Philos. Mag. A* 82, 2855–2867, with permission from Taylor & Francis Ltd., <http://www.tandf.co.uk/journals>.

indication of glide dissociation (Bodur *et al.*, 2005). The Peierls mechanism has also been invoked to explain the different dislocation glide mobilities for the two kinds of slip, and to calculate curves of CRSS versus temperature which are consistent with experimental data (Mitchell and Heuer, 2004). Because of difficulties with fitting parameters, more elaborate models (Mitchell *et al.*, 2003) have been used to achieve satisfactory descriptions of the experimental data (Castillo Rodriguez *et al.*, 2007).

Dislocation motion has been found to be enhanced by the presence of hydrogen, inducing a large softening for the deformation of sapphire and alumina ceramics below 1000°C; this is analogous to the well-known hydrolytic weakening of quartz (Castaing *et al.*, 2000). The influence of impurities (Mg, Ti, Cr) has also been studied (Mitchell and Heuer, 2004); for rubies with various Cr concentrations, basal slip is still dominated by the Peierls mechanism (Castillo Rodriguez *et al.*, 2007).

Silicon Carbide

Silicon carbide has two different types of applications. First, its excellent properties above 1000°C make it largely used as a structural ceramic. Second, SiC is a semiconductor with a bandgap of 2.4 eV or more, which can be included in high-power devices for use at temperatures much higher than conventional semiconductors. Silicon carbide is the only compound that forms in the Si–C phase diagram; it exists in more than 200 polytypes or stacking arrangements along the direction of close packing. There is one cubic polytype named β -SiC, corresponding to the stacking of three different layers, like other compounds with the zinc blende structure; for this reason, it is also named 3C-SiC. The noncubic polytypes are named collectively α -SiC. They have hexagonal (H) or rhombohedral (R) symmetry and are also named using the number of stacked layers along the close packing direction (Pirouz and Yang, 1993; Hong *et al.*, 2000). The most common polytypes are 4H-SiC and 6H-SiC which have become recently available as single crystals. In addition to the mechanical properties, the polytypic transformations are directly influenced by dislocations. The great variety of SiC ceramic materials explains the large number of investigations; we focus here on single-crystal studies.

Fujita *et al.* (1987) deformed 6H-SiC single crystals oriented for basal slip. The CRSS decreased from 70 MPa at 1100°C to about 10 MPa at 1600–1800°C; these stresses are remarkably small for a compound which is a major component of SiC structural ceramics. TEM examination of the deformed specimens revealed large numbers of $1/3 \langle 2 - 110 \rangle$ dislocations dissociated into $1/3 \langle 1 - 010 \rangle$ and $1/3 \langle 1 - 100 \rangle$ partials with large separations, indicating a low-energy stacking fault (2.5 mJ m^{-2}) (Maeda *et al.*, 1988). This opens the possibility for the glide of single partial dislocations, with an applied shear stress of 14 MPa providing enough mechanical work to generate stacking faults. Recently, Samant and Pirouz (1998) performed similar compression-deformation experiments on 4H-SiC and 6H-SiC between 550°C and 1300°C. The CRSS increases sharply below 700°C where 6H-SiC becomes stronger than 4H-SiC (the CRSSs are 450 MPa and 235 MPa respectively, at 550°C); below 1100°C, the deformation of both polytypes takes place by nucleation and glide of partial dislocations alone. However, there is no clear explanation for the difference of strengths between 4H-SiC and 6H-SiC. Hong *et al.* (2000) found that the dissociation widths of dislocations introduced at 1300°C are quite different in the two polytypes, giving stacking fault energies of 2.9 mJ m^{-2} for 6H-SiC, in agreement with Maeda *et al.* (1988), and 14.7 mJ m^{-2} for 4H-SiC; the difference can be explained on the basis of the crystal structures. Similar types of observations were made on Al doped α -SiC deformed at 1950°C; dissociated dislocations were found

on the basal planes of 4H-SiC grains and a stacking fault energy of 14 mJ m^{-2} was deduced, in agreement with the value found for single crystals (Duval-Riviere and Vicens, 1994).

The existence of numerous polytypes and the easy movement of single partial dislocations, due to the low stacking-fault energies, suggest that the two phenomena are linked and that the polytypic transformation can be a consequence of partial dislocation glide, as suggested by the TEM observations of deformed α -SiC ceramics by Duval-Riviere and Vicens (1994). Pirouz and Yang (1993) describe the transformation mechanism whereby a partial dislocation changes the stacking sequence. If a second partial glides on a basal plane parallel to the first one, this can create a lamella of a new polytype. The partial dislocations can be created by a Frank–Read source, with the modification that after emitting the first partial, a second identical one cannot glide on the faulted plane; instead it has to cross-slip to the next available plane. After transformation of the crystal from one polytype to another, a residual dislocation is left on the cross-slip plane, that is, parallel to the $[0\ 0\ 0\ 1]$ axis in α -SiC. Pirouz and Yang (1993) demonstrated that this mechanism was operative by deforming a properly oriented 6H-SiC crystal, which was transformed into the 3C phase by compression at 1100°C and 1400°C . Similar ideas have been used to design mechanisms for twinning in various crystals, in particular for basal twinning in sapphire (see Section “Ductile Compounds”). The properties of partial dislocation Frank–Read sources are also taken into account to explain the brittle to ductile transition in SiC. Indeed, brittleness is associated with the occurrence of deformation microstructures built with numerous extended stacking faults (Pirouz *et al.*, 2003). It is postulated that, at low temperature, the ‘trailing’ partial eliminating the stacking faults associated to the dissociation of a perfect $1/3\ \langle 2 - 110 \rangle$ dislocations cannot be nucleated. Since the Frank–Read source cannot emit a second partial in the same plane, the source shuts, hence the brittle behavior.

Different types of dislocations gliding in the $(0\ 0\ 0\ 1)$ plane (or $(1\ 1\ 1)$ plane for 3C material) have been recognized in relation to their core structure. The extra half-planes can end at the dislocation cores on carbon or a silicon rows. In addition, as in cubic semiconductors, the shearing can take place between widely separated planes (shuffle set) or between closest planes (glide set). The dislocations in those planes can be either perfect, having an expected low Peierls potential (the shuffle set) or dissociated, having an expected high Peierls potential (the glide set). Experimentally the signature of the glide set is the observation of dissociated dislocations although no clear evidence has been put forward up to now of the actual core location.

In a given set, Si and C core have been distinguished using the LACBED TEM technique. It has been shown that the partial dislocations in 4H and 6H which yield to the formation of large extended stacking faults below the brittle to ductile transition temperature are usually Si ones which appear as the partials with the highest velocity (Pirouz *et al.*, 2001). The results of these observations are in disagreement with *ab initio* computations where the C partial is shown to have the highest velocity.

Applying a confining pressure, higher stresses than those usually investigated in 4H-SiC can be reached (Demenet *et al.*, 2005). The deformation microstructures are built not only with dissociated dislocations but also with perfect dislocations which are expected to be nucleated in the shuffle set. This has been also observed after nano indentation tests at room temperature (Texier *et al.*, 2013). Other experiments report that other type of perfect dislocations can be found below the BDT in the prismatic or first order pyramidal plane which suggests that dislocation nucleation can occur in those planes before cross slipping in the basal plane (Mussi *et al.*, 2006; Mussi *et al.*, 2007). More experiments are needed to understand the relation between dislocation nucleation mechanism, the core structure of dislocations and the brittle-to-ductile transition. Note also that in SiC 4H of electronic quality, the effect of electronic doping has been evidenced on dislocation mobilities, an effect similar to that obtained in elemental semiconductors (Demenet *et al.*, 2011).

Nitrides

There has been considerable work done on nitrides. Here, we consider a couple of them which are being increasingly used for various types of applications. Silicon nitride Si_3N_4 ceramics are well suited for structural applications such as heat exchangers or gas turbines; they are used commercially for car turbochargers. Aluminum nitride, AlN, has very good heat conduction, which is excellent for electronic substrates. The system AlN-GaN-InN provides unique possibilities for optoelectronic devices with band gaps between 2 eV and 6 eV; blue and green light emitting diodes (LEDs) are commercially available and are based on GaN containing various amounts of In or Al (Ponce and Bour, 1997). They are generally grown by chemical vapor deposition of epitaxial layers on $(0\ 0\ 0\ 1)$ sapphire substrates. Very surprisingly, the active layers of these LEDs contain dislocations in densities as high as 10^{10} cm^{-2} , which is more than six orders of magnitude greater than in other conventional semiconductor devices. The light efficiency of these GaN-based LEDs is remarkably insensitive to the presence of dislocations (Ponce and Bour, 1997).

There have been only a few attempts to introduce dislocations in AlN by plastic deformation. Audurier *et al.* (1998) deformed AlN ceramics by compression between room temperature and 800°C under 1 GPa hydrostatic pressure; the applied uniaxial stresses reached almost 4000 MPa. TEM observations have shown that both $(0\ 0\ 0\ 1)\ \langle 2 - 110 \rangle$ basal slip and $\{1 - 010\}\ \langle 12 - 10 \rangle$ prism plane slip have been activated. AlN has the hexagonal wurtzite structure; $1/3\ \langle 12 - 10 \rangle$, which is the shortest repeat distance (0.31 nm), is the Burgers vector. In the basal plane only screw dislocations, with the three $1/3\ \langle 2 - 110 \rangle$ Burgers vectors, are observed by TEM. This suggests that the Peierls stress on these dislocations is large. The configurations in the prism plane slip are more diverse. There are many reactions and cross-slip events, which are expected for multiple slip in a polycrystal. Prism plane slip could be easier than basal slip. Dislocation dissociation has not been observed by weak-beam TEM. These preliminary observations on AlN do not coincide with those made on homoepitaxial GaN layers by Ponce *et al.* (1996); they found three Burgers vectors, namely $1/3\ \langle 12 - 10 \rangle$, $1/3\ \langle 1 - 1 - 23 \rangle$, and $[0\ 0\ 0\ 1]$, and considerable evidence for dissociation. The mechanism of dislocation multiplication during epitaxial growth has not yet been elucidated.

Fig. 4 AFM images of glide lines in β - Si_3N_4 indented at room temperature. (a) General view, (b) enlargement of the surrounded area in (a). Step heights correspond to the output of a few dislocations with $[0\ 0\ 0\ 1]$ Burgers vectors. Reproduced from Milhet, X., Girard, J.C., Demenet, J.L., Rabier, J., 2001. Characterization of room temperature plastic deformation of β - Si_3N_4 by atomic force microscopy and transmission electron microscopy. *Philos. Mag. A* 81, 623–629, reprinted by permission of Taylor & Francis Ltd., <http://www.informaworld.com>.

Silicon nitride ceramics are generally mixtures of Si_3N_4 and glasses which result from the oxides (MgO , Al_2O_3 , etc.) added during processing to promote densification. The softening of the glass phase has probably prevented the observation of dislocations after high-temperature deformation of silicon nitride. Milhet *et al.* (1999) have used compression tests at 850°C under 1 GPa hydrostatic pressure to induce dislocations in Si_3N_4 grains of sintered ceramics. The specimen failed at a uniaxial stress of 2850 MPa. Thin foils for TEM were prepared from regions near the cracks generated by the mechanical test. The dislocations in the microstructure had $[0\ 0\ 0\ 1]$ Burgers vectors. They were generally screw in character and in the form of elongated loops, from which it was concluded that the mobility of screws were smaller than that of edges due to differences in the Peierls stress. The two $\{1\ 010\}$ and $\{12\ 10\}$ planes have been suggested as glide planes. Extension of the dislocation core in the six possible slip planes has been suspected. Dislocations have been observed in grains of the high-temperature β - Si_3N_4 phase, possibly because β - Si_3N_4 is softer than α - Si_3N_4 or possibly because β -type grains are bigger than α -type grains and therefore easier to find for TEM examination. The crystal structure of β - Si_3N_4 can be represented using hexagonal unit cells with dimensions $a = 0.77\text{ nm}$ and $c = 0.29\text{ nm}$, $[0\ 0\ 0\ 1]$ being indeed the shortest repeat distance. The unit cell of the α -phase is also hexagonal, with c being twice that for the β -phase: c dislocations have consequently higher strain energies in the α -phase than in the β phase.

Although these compounds were considered to be brittle at room temperature, dislocations motion has been found to occur during indentation tests conducted at room temperature on β - Si_3N_4 . This was probed by using atomic force microscopy (AFM) a technique able to evidence slip lines with an excellent resolution (see Fig. 4). Such images were used to characterize glide lines corresponding to the emergence of a few dislocations as well as cross-slip (Milhet *et al.*, 2001).

From these various studies, it is clear that dislocations in silicon nitrides can contribute to plasticity more than what is usually thought. There is still a lot to learn about dislocations in these compounds.

Superconductors

The discovery in 1986 of superconductors with high critical transition temperatures promoted intense research activity on these compounds and great expectations for applications. However, many limitations have appeared, mostly because of the chemical instability and the brittleness of the compounds. The best-known of those so-called high- T_c superconductors is certainly $\text{YBa}_2\text{Cu}_3\text{O}_7$ whose high temperature phase $\text{YBa}_2\text{Cu}_3\text{O}_6$ is not superconducting so that an oxygenation step is required after high-temperature annealing. Furthermore, $\text{YBa}_2\text{Cu}_3\text{O}_7$ is unstable as compared to $\text{YBa}_2\text{Cu}_4\text{O}_8$, so that additional CuO atomic layers are easily nucleated in the material. The challenge is to reach critical currents in superconductors that are as high as possible. Dislocations are interesting defects for high- T_c materials. Indeed, differently from usual “low- T_c ” superconductors, high- T_c materials possess low correlation lengths, which are of the order of the core extension length of dislocations. Then single dislocations are potential pinning centers for vortices. The microstructures of those materials are usually complex, built with a variety of extended defects (Fig. 5) but can be modified by various thermomechanical treatments. In this context, Sandiumenge *et al.* (2000) have reviewed the different ways to optimize flux pinning in textured $\text{YBa}_2\text{Cu}_3\text{O}_7$ or similar compounds.

Fig. 5 TEM image of the as-grown microstructure of a melt textured grown $\text{YBa}_2\text{Cu}_3\text{O}_7$: mirror twin boundaries (MTB), dislocations interacting with MTB, second phase inclusion 211 $\text{Y}_2\text{Ba}_1\text{Cu}_1\text{O}_5$. Picture: courtesy of Plain J.

Rabier *et al.* (1993) were able to deform polycrystals under hydrostatic pressure in the superconducting phase; dislocations were usually not dissociated. If, in addition to room-temperature deformation, the specimens are subjected to a thermal treatment (900°C for 24 h, cooled and maintained at 450°C for 4 h, in air), the dislocation structure is completely changed, with very large dissociation widths associated to additional CuO layer, that is, a “nonstoichiometric dissociation”. This shows that dislocations act as nuclei for CuO precipitation. Conventional high-temperature deformation in the ductile regime tends to degrade the superconducting performance, with a decrease in critical current, even after annealing in oxygen to restore the superconducting phase (Vilalta *et al.*, 1997). Other processes were studied to create dislocations in the superconducting phase in order to avoid the oxygenation step and preventing crack nucleation: cold isostatic pressing (CIP) and annealing under high oxygen pressure (HOP). CIP yields to dislocation multiplication at elastic discontinuities in the solid resulting in increases in the critical current (Martinez *et al.*, 1999). Using HOP (Plain *et al.*, 2002a), it is possible to monitor the dislocation density and improve the critical current densities (Plain *et al.*, 2002b). This dislocation engineering process relies upon the instability of the material versus $\text{YBa}_2\text{Cu}_4\text{O}_8$ so that the microstructures after HOP annealing are built with partial dislocations bounding a nonstoichiometric stacking fault. It was possible to probe the effect of partial dislocations and the associated stacking faults on the critical current. It is shown that the pinning efficiency is maximum when the stacking fault surface is minimum and the length of the partial dislocations maximum. Indeed, dislocations act as point pinning centers, whereas stacking faults lead to diminish the coherence length along the vortices. The optimum in critical current density was realized when the ratio dislocation length over stacking fault surface is maximum.

In all these microstructures obtained, dislocations are found to be located in the (0 0 1) easy glide plane, as well as the nonstoichiometric stacking faults while the ideal orientation for flux pinning is perpendicular to it. Compounds with Nd, instead of Y, have been shown to have glide planes perpendicular to (0 0 1) (Sandiumenge *et al.*, 1998); they could be more convenient for vortices pinning by dislocations.

Conclusions

Dislocation multiplication can occur in ceramic materials by the application of stresses. We have examined here a number of typical cases, but have not covered the whole field. Other important materials have received attention, such as UO_2 , Cu_2O , quartz, garnets, etc. The questions raised by dislocations in ceramics are very close to those concerning the dislocations responsible for the deformation of rocks and minerals. These types of studies have benefited from those performed on dislocations in metals and in semiconductors. However, there are various specific questions which are still unsolved. For instance, the energies of dislocations in ceramic materials are so large that they have to be decreased by dissociation, observed by TEM, or by core extensions. Climb dissociation has been found more frequently than in any other classes of materials. This is probably due to the high temperatures necessary to activate dislocation motion; atomic diffusion also increases at such temperatures. Climb dissociation does not have always a well-understood influence on the plastic properties of ceramic materials. There are many examples where extension of the core is suspected and not observed directly. Up to date TEM techniques such as high-resolution TEM and STEM equipped with aberration correctors have to be used extensively and coupled with atomistic simulations in order to shed new light on the properties of dislocations in ceramics.

Corrosion of Ceramics in Aqueous Environments

Mathias Herrmann, Fraunhofer Institute for Ceramic Technologies and Systems, Dresden, Germany

© 2021 Elsevier Inc. All rights reserved.

The term “corrosion” is defined for ceramics as well as for metallic or polymeric materials as a local or large-area reaction of a material with a surrounding medium, which can lead to degradation of the material or component up to its destruction. Corrosion stability is therefore not a property of the material per se, but a property of the system and requires not only the specification of the material but also the specification of the respective conditions (e.g., medium, temperature, pressure, flow conditions, additional mechanical and tribological load) (ISO, 2020; Clark and Zito, 1992; McCauley, 1995; Brevier *Technische Keramik*, 2020; Nickel and Gogotsi, 2000; Schilm and Herrmann, 2010; Herrmann and Klemm, 2014; Herrmann, 2013a; Frankel *et al.*, 2018; Chevalier *et al.*, 2009; Clark *et al.*, 1976; Paul, 1977). Textbooks therefore usually list the corrosion resistance for standard conditions. For special applications it must be decided whether these conditions can be transferred or whether separate corrosion investigations are necessary.

To assess the corrosion behavior of a ceramic in advance, it is necessary to evaluate its stability against aqueous media from both thermodynamic and kinetic points of view. While thermodynamics provides basic information about the possibility (Gibbs free energy of reaction $\Delta G_{\text{reaction}} < 0$) or impossibility of a corrosive attack ($\Delta G_{\text{reaction}} \gg 0$), kinetic considerations provide information about the rate of the reaction. For example, the thermodynamic instability of Al_2O_3 ceramics in acids is countered by a very low dissolution rate, which is responsible for an extremely slow corrosive attack. This makes high-purity corundum ceramics stable in these media.

To understand the corrosion behavior, it is advantageous to divide ceramics into two main groups:

- Solid state sintered materials with high purity and low content of secondary phases (high purity Al_2O_3 ; ZrO_2 ; SiC , TiO_2 , YAG, spinel) and
- Liquid phase sintered or infiltrated ceramics with a higher proportion of grain boundary phase (silicon nitride ceramics (Si_3N_4); liquid phase sintered SiC (LPSSiC); AlN ; porcelain; Al_2O_3 with glass phase, silicon infiltrated silicon carbide (SiSiC), cermets; WC/Co).

Fig. 1 shows microstructures of one representative of each of these two groups and additionally the picture of a reactive infiltrated material.

The processes taking place during corrosion in liquids in both types of ceramics are shown schematically in **Fig. 2**.

In contrast to the solid state sintered materials, the liquid phase sintered materials have an amorphous, partially crystalline, or crystalline grain boundary phase, which normally forms a three-dimensional skeleton. This means that the corrosive attack can damage the material to great depths if the grain boundary phase is less stable than the main phase. Therefore, the properties of the grain boundary phase often determine the corrosion stability of liquid phase sintered ceramics. Small changes in the amount and composition of the grain boundary phase can therefore cause strong changes in the corrosion stability.

Fig. 3 demonstrates the strong reduction in corrosion stability with increasing amount of grain boundary phase (increasing amounts of SiO_2) for corundum ceramics. **Fig. 4** shows the change in mass as a function of time for Si_3N_4 -ceramics with different additive compositions, i.e., different grain boundary compositions. It is shown that the choice of additives can change the stability of the ceramics by several orders of magnitude.

In contrast, the solid state sintered ceramics show only minimal segregations of impurities or dopants at the grain boundaries. These segregations do not form a three dimensional network and therefore the difference in chemical stability of the impurities has a minor impact on the overall corrosion behavior, but could result in local enhanced corrosion pitting (see below) and could be a reason for strength reduction.

Compared to metals, in which corrosion takes place via redox reactions with locally separated cathodic and anodic reactions and local electrical currents flow, the corrosion of ceramics is generally not characterized by any change in the oxidation state of the components involved (exception e.g., SiC and other carbides). The reactions taking place are acid-base reactions (Eq. (1)), hydration of metal oxides (Eq. (2)) or the hydrolysis of covalent bonds (Eq. (3)).

These processes are comparable to the dissolution of passivating protective layers on metals. Therefore, compared to metallic materials, technical ceramics are usually more corrosion resistant.

The amount of corrosion is often determined as mass change per unit area, thickness of the corroded or removed layer, or as the accumulation of individual components in the eluate as a function of time. (McCauley, 1995; Nickel and Gogotsi, 2000; Schilm and Herrmann, 2010; ISO, 2006; Galuskova *et al.*, 2014; Striegler *et al.*, 2018).

Fig. 1 (a) Microstructure of solid state sintered silicon carbide (SSiC) (locally isolated pores and black inclusions (carbon and boron carbide) are visible), (b) Liquid phase sintered Si_3N_4 ceramics, the white area is the grain boundary phase forming a three-dimensional network, (c) Silicon infiltrated silicon carbide (SiSiC), the white phase is elemental Si forming a three-dimensional network around SiC (gray).

The most powerful method is the determination of the residual strength in combination with analysis of the fracture surfaces. In addition to the rate of integral corrosion, conclusions can also be drawn about locally increased corrosion (pitting) and the reduction of strength due to corrosion. This is important because structural materials are often subjected to mechanical stress in addition to chemical attack. However, this is also the most expensive method because a high number of samples is necessary. The methods are summarized in (Nickel and Gogotsi, 2000; Schilm and Herrmann, 2010; ISO, 2006) and Table 1.

As a rule, several reactions or mass transport processes are involved in a corrosive attack, which depend in different ways on the surrounding parameters (e.g., temperature, concentration ratios in the corrosive medium, composition and the quantity of the grain boundary phase). The superposition of these individual processes often results in complex time dependencies of the corrosion processes, which are determined by the slowest, and thus rate-determining process. (Clark and Zoitos, 1992; McCauley, 1995; Nickel and Gogotsi, 2000; Herrmann and Klemm, 2014; Frankel *et al.*, 2018).

Fig. 5 schematically shows three typical dependencies of corrosion processes as a function of time.

The typical time dependencies of corrosion processes are:

- linear dependence on time for interface-controlled processes. The corrosion depth X can be calculated by the equation

$$X = K t + C \text{ with } K = K_0 e^{\frac{-E}{RT}} \quad (4)$$

Fig. 2 Schematic view of the corrosion processes taking place in liquid phase sintered materials (a) and solid state sintered materials (b). After Schilm, J., Herrmann, M., 2010. Korrosion in wässrigen Medien. In: Kollenberg, W. (Ed.), Technische Keramik, 2. Auflage. Essen: Vulkan Verlag, pp. 102–106.

Fig. 3 Mass losses of corundum ceramics depending on the SiO_2 content (corrosion conditions: 1N HCl 150°C, 96 h). Reproduced from Herrmann, M., Klemm, H., 2014. Corrosion of ceramic materials. In: Comprehensive Hard Materials, second ed. Newnes, pp. 413–446.

with K – reaction constant, which may additionally depend on the concentration of the reacting species. t – time, E – activation energy and R – general gas constant and T – temperature, C is a constant that adds up initial surface effects, or corrosion up to time $t = 0$ (e.g., during heating up).

- parabolic dependence on the time takes place when diffusion processes determine the rate.

$$X^2 = K t + C \text{ with } K = K_0 e^{\frac{-E}{RT}} \quad (5)$$

(designation analogous to Eq. (4)).

- If additional passivation reactions occur, the reaction slows down over time even more than in the diffusion-controlled process. Such passivation takes place by precipitation of solid phases which are deposited in the corroded ceramic or on its surface, which can lead to the formation of highly protective layers (Figs. 5 and 2).

Fig. 4 Corrosion of Si_3N_4 ceramics with different kind and amount of additives in 0.5 mol/l H_2SO_4 and 90°C (the labeling shows the kind of additives (Mg: MgO , Al: Al_2O_3 , Y: Y_2O_3 , Si: SiO_2) and the number corresponds to the volume percentage content). Reproduced from Herrmann, M., Klemm, H., 2014. Corrosion of ceramic materials. In: Comprehensive Hard Materials, second ed. Newnes, pp. 413–446.

Table 1 Overview of assessment methods

Nr	Evaluation procedure	Comment	Examples
1	Strength change	Expensive, as many samples are required per condition; must be coupled with determination of the strength in order to determine defects and thickness of the corrosion layer (fractography)	Suitable for all materials
2	Depth of penetration (Depth of damage)	Suitable for all types of corrosion; Preparation of polished cross sections required (dye penetration test can be useful); sometimes corrosion depth can be determined at fracture surfaces (method1)	Si_3N_4 ; Al_2O_3 ; SiC, WC/Co, Cermets
3	Change of test piece size (layer thickness)	Often unsuitable, because not accurate enough, removal by corrosion must be $> 5 \mu\text{m}$, suitable for growing layers, but then analysis of cross sections/fracture surfaces necessary	Glasses Oxidation processes of non-oxides
4	Specific mass change	Suitable for surface corrosion, for interpretation the analysis of the damage depth is useful. Is influenced by the sample geometry (shrinking core effect)	Si_3N_4 ; SiC Not suitable for ZrO_2 materials
5	Change of the composition of the corrosion medium	Suitable for corrosion with solution processes especially for liquid phase sintered materials	Not suitable for ZrO_2 -materials
6	Phase change	Standard for ZrO_2 materials, (e.g., for medical materials ISO 13356:2015)	ZrO_2 -materials (TZP, PSZ)
7	Change of the surface morphology	Suitable for understanding the corrosion mechanisms in the initial phase; (use of polished surfaces)	Liquid phase sintered materials; SiSiC

Soc. 94, 3035–3043. doi:10.1016/j.matchar.2011.01.012.

- The rate of corrosion can also be controlled by diffusion in the surrounding media or slow down due to enrichment of the solved species in the solution. This results in more complex reaction kinetics (Clark and Zitois, 1992; McCauley, 1995; Nickel and Gogotsi, 2000; Frankel et al., 2018; Herrmann, 2013b).

Fig. 6 Time dependence of the thickness of the corrosion layer on a Si_3N_4 -ceramic as a function of temperature in 0.5 mol/l H_2SO_4 (Si_3N_4 -material with 6 wt% Y_2O_3 and 4 wt% Al_2O_3). Reproduced from Herrmann, M., Klemm, H., 2014. Corrosion of ceramic materials. In: Comprehensive Hard Materials, second ed. Newnes, pp. 413–446.

For plate like shapes of the samples or under the condition that the corrosion depth is low in comparison to the sample dimensions, the Eqs. (4) and (5) can also be used for describing the mass change as a function of time. In other cases, the geometry must be considered (shrinking core effect) (Herrmann, 2013b; Schilm, 2004).

Knowing the activation energy, the result determined at higher temperatures can be extrapolated to lower temperature. This allows the prediction of the long-term behavior of a component based on the laboratory experiments. The precondition for such extrapolation is, that the mechanism does not change.

The mechanism can depend on the composition of the material and on the corrosion conditions. Fig. 6 shows an example of Si_3N_4 ceramics. An increase in temperature of only a few K changes the mechanism of corrosion in 0.5 mol H_2SO_4 from an interface-controlled reaction at $T < 75^\circ\text{C}$ to passivation of the ceramic after an initial starting period at $T > 83^\circ\text{C}$. The passivation is caused by the formation of SiO_2 rich deposits in the leached grain boundaries. The result of the mechanism change is that the sample corroded at a higher temperature (e.g., 90°C) is attacked less than the sample corroded at 75°C for corrosion times > 200 h. (Herrmann and Klemm, 2014; Herrmann, 2013b; Schilm, 2004) The example shows that kinetics are sometimes very complex and therefore, the prediction of the behavior over long periods of time requires a precise determination of the mechanism.

In addition, the corrosion behavior often depends strongly on the concentration of the reagents. Fig. 7 shows the dependence of the corrosion of a Si_3N_4 ceramic as a function of the concentration of H_2SO_4 . The data reveal that in concentrated and dilute H_2SO_4 the

Fig. 7 Time dependence of weight loss on corrosion time for a Si_3N_4 material with 6 wt% Y_2O_3 and 4 wt% Al_2O_3 in H_2SO_4 with different concentrations at 90°C (concentrations given in the diagram). Fig. 8 Increase of the subcritical crack growth rate of ceramics by chemical reactions with water. (a) schematic illustration of the interaction with H_2O , which leads to increased breaking of the bonds in the ceramic and thus to increased subcritical crack growth (M- metal e.g., Al, Zr). (b) Schematic illustration of the dependence of the logarithm of the crack growth rate on the stress intensity factor and the surrounding media. Adapted from Aza, A.H., Chevalier, J., Fantozzi, G., 2002. Crack growth resistance of alumina, zirconia and zirconia toughened alumina ceramics for joint prostheses. *Biomaterials* 23, 937–945.

attack is much less than in acids of medium concentration. The higher stability in concentrated acids is due to the low solubility of SiO_2 from the grain boundary phase in these media. This leads to a passivation by the formation of poorly soluble SiO_2 layers. Similar behavior was observed for alumina ceramics (Herrmann and Klemm, 2014; Herrmann, 2013b; Schilm, 2004; Sato *et al.*, 1991).

Besides the integral corrosion stability, local corrosion plays a decisive role. Such local damage of the ceramic is called pitting. It is enhanced corrosion at inhomogeneities of the material and essentially determines the strength of the materials after corrosion (residual strength), since defects close to the surface are rapidly increased. The reduction in strength is particularly intensive in the initial phase of corrosion and is strongly influenced by local inhomogeneities, pores or other defects existing in the material. (Herrmann and Klemm, 2014; Herrmann, 2013a; Striegler *et al.*, 2018; Herrmann, 2013b; Schilm, 2004).

Since ceramic components are usually not only chemically stressed but also tribologically or mechanically stressed, the determination of the residual strength is of great importance for the selection of materials for specific applications.

Mechanical stress below the critical stress, which leads to fracture, can lead to failure after a certain time. The reason is the subcritical growth of existing defects. This subcritical crack growth is intensified by load and corrosion (Freiman *et al.*, 2009; Aza *et al.*, 2002; Barsoum, 2003). This is shown schematically in Fig. 8(a). Even moisture increases the subcritical crack growth in

Table 2 Stabilities of different technical ceramics in aqueous solutions

Material	Medium	Stability	Notes
Al ₂ O ₃ (> 99.9%)	H ₂ SO ₄ ; HCl; < 100°C NaOH; H ₂ O ≤ 100–200°C	high	Stability could be influenced by impurity content
Al ₂ O ₃ (< 99.9%)	H ₂ SO ₄ ; HCl, NaOH, H ₂ O	Lower than pure Al ₂ O ₃	Corrosion resistance is determined by the composition of the grain boundary phase. SiO ₂ in the material reduces the stability
ZrO ₂ CSZ (8Y-SZ)	H ₂ SO ₄ > RT H ₂ O (including hydro-thermal conditions and water vapor)	high	Show a very low solubility in the media, the cubic phase does not transform
ZrO ₂ Y-TZP	H ₂ SO ₄ > RT H ₂ O > 100°C	Low, medium	Degradation of the ceramic material occurs due to stress caused by a corrosion-related transformation to monoclinic ZrO ₂
Mg-PSZ Ce-TZP	H ₂ SO ₄ > RT H ₂ O < 200°C	higher than Y-TZP	Material is much less prone to degradation than Y-TZP
ZTA (10–15 wt% ZrO ₂)	H ₂ SO ₄ ; NaOH < 100°C H ₂ O > 200°C	high medium	Material exhibits almost no degradation if it is free of SiO ₂ Degradation of the ceramic material occurs due to stress which is caused by a corrosion-related transformation to monoclinic ZrO ₂
SiC	acid; bases HF Electrochemical attack possible	high	Depends on the conductivity of the material
SiSiC	acids HF bases, hydrothermal	high low low	In acid passivation of Si by SiO ₂ formation Dissolution of free silicon Dissolution of free silicon
LPSSiC	acid; bases hydrothermal	medium or high	Corrosion resistance is strongly dependent upon the composition and distribution of the grain boundary phase and defects
Si ₃ N ₄	concentrated HCl, HNO ₃ , H ₂ SO ₄ diluted acids, bases	high stability high or low	SiO ₂ surface layer formation results in passivation Stability depends on the amount and composition of the grain boundary phase
	H ₂ O < 200°C HF	very low medium/low	Dissolution of grains and grain boundary phase occurs Stability depends on the amount and composition of the grain boundary phase
	H ₂ O > 200–250°C		Increased dissolution of Si ₃ N ₄ grains occurs
WC/Co/Cermets	acids	low	Dissolution of the metallic binder Ni containing materials more stable than Co containing systems
	electrochemical Corrosion	low, medium	Dissolution of the binder in acidic solutions and WC in basic solutions

Note: After Schilm, J., Herrmann, M., 2010. Korrosion in wässrigen Medien. In: Kollenberg, W. (Ed.), Technische Keramik, 2. Auflage. Essen: Vulkan Verlag, pp. 102–106. Herrmann, M., Klemm, H., 2014. Corrosion of ceramic materials. In: Comprehensive Hard Materials, second ed. Newnes, pp. 413–446.

comparison to inert conditions (Fig. 8(b)). The effect is more intensive in aqueous solutions and at elevated temperatures. The local chemical corrosion at the crack tip can increase the crack growth rate by several orders of magnitude, which leads to a drastic reduction in service life. The subcritical crack growth depends on the material and the microstructure, whereby oxide ceramics tend to have a stronger tendency to subcritical crack growth than SiC- and Si₃N₄-ceramics.

The influence of superimposing wear and corrosion is still not investigated in detail due to the wide range of possible parameters. In general, the wear reduces the corrosion resistance.

Table 2 provides a rough overview of the corrosion behavior of various important technical ceramics. As was explained before, the intensity of the corrosive attack can vary greatly depending on the composition, especially the grain boundary phase.

The Fig. 9 gives a comparison of the change of strength as a function of the corrosion conditions for different materials.

In the following paragraphs, some corrosion aspects for the individual ceramics will be dealt with briefly.

Corundum Ceramics (Clark and Zoitos, 1992; Herrmann and Klemm, 2014; Galuskova *et al.*, 2011a,b; Mikeska *et al.*, 2000; Mikeska, 1999)

High-purity corundum ceramics have a high chemical stability in most media. An indication of the high stability is the unchanged strength independent of the corrosion conditions. If the ceramic contains grain boundary phases, these can have a

Fig. 9 Residual strength of different ceramics after 200 h corrosion in 1 mol NaOH (130°C) and 0.5 Mol/l H₂SO₄ (100°C) and under hydrothermal conditions in water at 200°C (SiSiC (silicon infiltrated SiC) was measured at 90°C. The hydrothermal corrosion of SiSiC at 200°C resulted in destroyed samples). Data from Herrmann, M., Klemm, H., 2014. Corrosion of ceramic materials. In: Comprehensive Hard Materials, second ed. Newnes, pp. 413–446. Striegler, M., Matthey, B., Mühle, U., Michaelis, A., Herrmann, M., 2018. Corrosion resistance of silicon infiltrated silicon carbide (SiSiC). *Ceram. Int.* 44, 10111–10118. doi:10.1016/j.ceramint.2018.02.229. Herrmann, M., Kluge, E., Rödel, C., McKie, A., van Staden, F., 2014a. Corrosion behaviour of silicon carbide diamond composite materials in aqueous solutions. *J. Europ. Ceram. Soc.* 34, 2143–2151.

strong influence on the chemical stability (Fig. 3). Silicate grain boundaries typically show low stability in mineral acids. The formation of crystalline Mg- or Ca-containing aluminates as secondary phases leads to a much lower damage during corrosion. Therefore, when assessing corundum materials that contain 0.5%–20% of silicates (Herrmann and Klemm, 2014; Galuskova *et al.*, 2011a,b; Mikeska *et al.*, 2000; Mikeska, 1999), the chemical composition of the secondary phases must always be taken into account.

Porous membranes usually consist of transition aluminas, which have a lower stability in comparison to corundum. In addition, the high surface of such filter materials influences the stability (Dong *et al.*, 2011).

ZrO₂ ceramics (Chevalier *et al.*, 2009; Aza *et al.*, 2002; Lawson, 1995; Lughi and Sergo, 2010; Keuper *et al.*, 2013)

ZrO₂ has 3 different modifications at normal pressure, which transform into each other:

The transformations are accompanied by a change in volume, which has a strong effect on the behavior of the ceramics (transformation toughening). The cubic and tetragonal modification can be stabilized with different amounts of rare earth or alkaline earth oxides. Based on the composition and the phases different classes of ceramics are formed which have different properties.

Cubic stabilized zirconia (CSZ) or fully stabilized zirconia (FSZ) is based on the cubic phase and often contains 8 mol% Y₂O₃ (8YSZ). Cubic ZrO₂ is very stable in aqueous media due to its low solubility up to high temperatures. Therefore, only extremely small mass changes occur during the ageing process. However, it has a relative low strength.

The ZrO₂ ceramics materials with high strength and toughness are TZP – *Tetragonal Zirconia Polycrystal*, PSZ – *Partially Stabilized Zirconia*. They are based on the metastable tetragonal phase. The corrosion stability of these ceramics is not primarily linked to the dissolution of ZrO₂. The stability is related to the stability of the metastable tetragonal phase. In hot acids, bases and under hydrothermal conditions a chemically induced transformation of the metastable tetragonal ZrO₂ grains (*t*-ZrO₂) into the monoclinic phase (*m*-ZrO₂) takes place. The destabilization is caused by the diffusion of water or OH-ions into the *t*-ZrO₂ grains (oxygen vacancies in the lattice) (Chevalier *et al.*, 2009; Lawson, 1995; Lughi and Sergo, 2010; Keuper *et al.*, 2013; Johannes and Schneider, 2012). The phase transformation results in volume increase. The resulting stresses lead to the formation of micro-crack systems, which accelerate corrosion and, in the final consequence, lead to a disintegration of the ceramic. The mechanism of phase transformation, which is on the one hand intended to increase the toughness of the materials, leads to low temperature aging, i.e., the destruction of the ceramic in hot water based solutions and especially under hydrothermal conditions. This is particularly important for medical applications, e.g., in the dental field. For this reason, attempts have been made to increase the stability through various material modifications. Fig. 10 gives an indication.

Fig. 10 Content of the monoclinic zirconia phase after ageing in steam at 134°C as a function of time and extrapolation to the degree of conversion at 37°C using activation energy (10Ce-TZP CeO₂ stabilized TZP, A10Z0Y – Zirconia toughened alumina (ZTA) with 10% unstabilized ZrO₂. The thickness of the corroded layer (m-ZrO₂-content) in 3YTZP ceramics depends linearly on time. Adapted from Chevalier, J., Gremillard, L., Virkar, A.V., Clarke, D.R., 2009. The tetragonal–monoclinic transformation in zirconia: Lessons learned and future trends. *J. Am. Ceram. Soc.* 92, 1901–1920. doi:10.1111/j.15512916.2009.03278.x. Keuper, M., Eder, K., Berthold, C., Nickel, K.G., 2013. Direct evidence for continuous linear kinetics in the lowtemperature degradation of Y-TZP. *Acta Biomater.* 9, 4826–4835.

CeO₂ doped TZP or Mg-partially stabilized ZrO₂ (Mg-PSZ), which show a lower transformation rate $t\text{-ZrO}_2 \rightarrow m\text{-ZrO}_2$ under the same conditions, are correspondingly more corrosion resistant (Chevalier *et al.*, 2009). The degradation of strength is moderate in hot H₂SO₄ and under hydrothermal conditions. (Fig. 9).

The healing of defects or small pores in Y-TZP-ceramics by post HIP processes increases the resistance significantly too. A reduction of the ZrO₂ grain size or the addition of Al₂O₃ also increases the chemical stability of the materials (Johannes and Schneider, 2012).

The stability of zirconia toughened materials (like zirconia toughened alumina (ZTA)) strongly depends on the amount of zirconia, the concentration of the stabilizer and distribution of the ZrO₂. The stability depends on the ability of the matrix to withstand the stresses caused by the transformation. Sometimes the strength of the material even increases due to the compression surface stresses generated by the chemically induced phase transformation.

Si₃N₄ ceramics (Herrmann and Klemm, 2014; Herrmann, 2013b; Schilm, 2004; Galuskova *et al.*, 2011a,b)

The stability of Si₃N₄ ceramics (see microstructure in Fig. 1(b)) depends very much on the composition of the grain boundary phase. The stability in acids can vary by several orders of magnitude depending on the composition of the grain boundary phase (Fig. 4). In concentrated alkaline solutions at elevated temperatures and under hydrothermal conditions > 200°C, SiO₂ passive layers on the Si₃N₄ grains dissolve, making the ceramic unstable. (Herrmann, 2013b).

Most commercial materials sintered with Y₂O₃ and Al₂O₃ additives show good stability in water and alkaline solutions, but lower stability in hot acids. This instability can be minimized by a specific design of the grain boundary phase (Fig. 4) (Herrmann, 2013b; Schilm, 2004). The corrosion stability of Si₃N₄ and Sialon ceramics is summarized in (Herrmann, 2013b; Schilm, 2004).

In media containing hydrofluoric acid, Si₃N₄ ceramics, like most ceramics containing Si, are not stable, as the formation of soluble SiF₆²⁻ complexes destroys the typical SiO₂-passivation layer and therefore dissolve the Si₃N₄ grains. The only exception is SSiC. (Herrmann, 2013b; Schilm, 2004; Mikeska *et al.*, 2000; Schmalzried and Schwetz, 2010).

The corrosion behavior of silicate ceramics is like that of Si₃N₄ ceramics. The corrosion in acids, bases and under hydrothermal conditions is mainly determined by the quantity and composition of the grain boundary phase. The stability of the grain boundary phase could be predicted by the results of glass corrosion (Clark and Zito, 1992; Clark *et al.*, 1976; Paul, 1977). In HF solutions the main components dissolve. Therefore, in HF containing solutions the stability is low.

SiC ceramics

(Schmalzried and Schwetz, 2010; Meschke and Kailer, 2004; Kitaoka *et al.*, 1994; Presser *et al.*, 2009; Gogotsi, 1994; Sydow *et al.*, 2010; Herrmann *et al.*, 2015; Striegler *et al.*, 2018).

Solid state sintered SiC ceramics (SSiC) (see microstructure in Fig. 1(a)) are the ceramics which are typically used when universal chemical resistance in aqueous media is required (e.g., bearings and seals of chemical pumps). SSiC shows a high chemical stability even in hydrofluoric acid (Schmalzried and Schwetz, 2010). Due to the good tribological properties and the high corrosion resistance, SSiC is used as bearing and sealing material (Schmalzried and Schwetz, 2010; Meschke and Kailer, 2004; Presser et al., 2009).

The SiC reacts under hydrothermal conditions in different ways:

In the temperature range of 100–200°C it reacts in water predominantly according to (Kitaoka et al., 1994)

and partially

Additionally, at 300°C, C₂H₆ (less than 1% of the amount of H₂), CO₂ and CO were observed in the gas phase indicating different reaction mechanisms. In the presence of dissolved oxygen in the water CO₂ and CO were dominant reaction products. Reaction (6) is a redox reaction whereas reaction (7) is simple hydrolysis. It has been shown, that by hydrothermal corrosion carbon layers can be formed on SiC and different carbides and metal carbide layers are formed by a treatment of MAX phases (Gogotsi, 1994; Anasori et al., 2017).

It can be stated that of all the common structural ceramic materials, solid state sintered silicon carbide (SSiC) has a universal stability in various media (Fig. 9). For this reason, and because of its favorable tribological properties, SiC is widely used for highly stressed bearings and seals (Herrmann, 2013a; Schmalzried and Schwetz, 2010; Presser et al., 2009).

Silicon infiltrated SiC ceramics (SiSiC) (see microstructure in Fig. 1(c)) are used for seals and bearings, partly because of their good tribological properties and low production costs for large components. However, SiSiC has a low stability in HF as well as in alkaline solutions and under hydrothermal conditions, as the free Si is dissolved by reaction

The formed SiO₂ has an increased solubility as silicates in alkaline solutions and as silicic acid under hydrothermal conditions.

The dissolution of the 3-dimensional network of Si is the reason for the observed strength reduction (Fig. 9).

The stability of *liquid phase sintered SiC (LPSSiC)* is determined by the oxide grain boundary phases formed. They are nearly fully crystallized (usually Y₃Al₅O₁₂; Al₂O₃, YAlO₃; and/or Y₄Al₂O₉) and are quite stable in acids and bases of medium concentration. However, the corrosion stability is somewhat lower than for SSiC. The formation of pits results in the reduction of strength (Fig. 9). (Herrmann and Klemm, 2014; Herrmann, 2013a; Schmalzried and Schwetz, 2010). Therefore, retention of the properties under corrosive conditions relates to minimization of defects (segregation of additives and pores).

Conductive ceramics such as SiC, other carbides or electrically conductive composite ceramics (e.g., Al₂O₃/TiC; Si₃N₄/SiC, Si₃N₄/TiN) may be subject to electrochemical corrosion in addition to pure chemical corrosion. These processes are very similar to the electrochemical corrosion processes of metals. However, the corrosion current densities are usually much lower (Sydow et al., 2010; Herrmann et al., 2015). The investigation of the electrochemical corrosion of SSiC ceramics revealed that in H₂SO₄ the reaction

is the dominant electrochemical reaction (Herrmann et al., 2014b).

Such electrochemical corrosion can cause corrosion under conditions where the material is otherwise stable. For example, local corrosion of SiC mechanical seals has been observed in deionized water. (Meschke and Kailer, 2004).

Conclusions

Overall, the corrosion behavior of ceramic materials in aqueous solutions is well understood. Modeling at different levels from atomic level to macro kinetics promises to deepen the understanding in the future (Frankel et al., 2018; Moras et al., 2011; Philippe and Vincent, 2017).

The existing knowledge can be used for the selection of materials for different applications. However, the corrosion behavior of the materials strongly depends on the existence and composition of small amounts of impurities, grain boundary phases (e.g., Si₃N₄; Al₂O₃-ceramics), grain size or dopants of the main component (especially ZrO₂ ceramic (TZP)) and the environmental conditions. The corrosion behavior is affected by superimposed tribological or mechanical load. Therefore, a careful selection of the materials for a given application must be carried out.
